Physics 371 lecture 31

Magnetic moment

Definition (classical)

$$\vec{\mu} = \frac{1}{2c}\int d^3r \left(\vec{r} \times \vec{J}_q(\vec{r}) \right)$$

QM:
$$\vec{J}_q = \frac{q}{2M}\left(\psi^* \frac{\hbar}{i}\nabla\psi - \psi \frac{\hbar}{i}\nabla\psi^* \right)$$
$$= \frac{q}{M}\,\mathrm{Re}\left[\psi^* \vec{p}\,\psi \right]$$

$$\langle \vec{\mu} \rangle = \frac{q}{2Mc}\int d^3r \left(\vec{r} \times \mathrm{Re}\left[\psi^* \vec{p}\,\psi\right] \right)$$

$$= \frac{q}{2Mc}\,\mathrm{Re}\int d^3r\; \psi^* (\vec{r} \times \vec{p})\,\psi$$

$$= \frac{q}{2Mc}\langle \vec{L} \rangle$$

Magnetic moment operator

$$\vec{\mu} = \frac{q}{2Mc} \vec{L}$$

Zeeman effect

Classically, $E = -\vec{\mu} \cdot \vec{B}$

$$\Rightarrow \quad \hat{H} = -\vec{\mu} \cdot \vec{B}$$

Say $\vec{B} = B\hat{z}$ (constant field)

$$\hat{H} = -\frac{qB}{2Mc} \hat{L}_z$$

magnetic quantum #

$$\hat{H} Y_{\ell m} = -\frac{q\hbar m}{2Mc} B \, Y_{\ell m}$$

mass

$$E_m = -\frac{q\hbar B}{2Mc} m \quad , \quad m = -\ell, \dots, \ell$$

- $$\Delta t \geq \frac{\hbar/2}{q\hbar B/2mc} = \frac{mc}{qB}$$

Classically, a magnetic field exerts torque on a magnetic moment:

$$\vec{\tau} = \vec{\mu} \times \vec{B} = \frac{d\vec{L}}{dt}$$

- Quantum mechanically, this equation of motion still holds on average:

$$\frac{d}{dt}\langle \vec{L} \rangle = \langle \vec{\mu} \rangle \times \vec{B}$$

HW: Prove this!

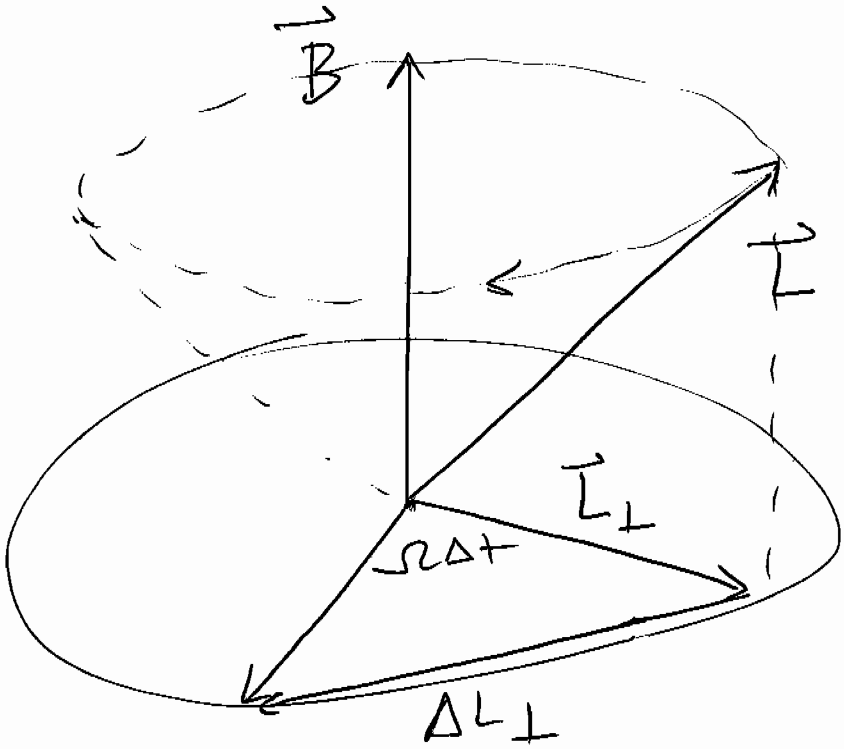
- $$\frac{d}{dt}\langle \vec{L} \rangle = -\frac{q\vec{B}}{2mc} \times \langle \vec{L} \rangle \equiv \vec{\Omega} \times \langle \vec{L} \rangle$$

- The average angular momentum vector precesses about the magnetic field with angular frequency

$$\boxed{\Omega = |\vec{\Omega}| = \frac{qB}{2Mc}} \quad \text{Larmor frequency}$$

$$\Omega \Delta t \geq \frac{qB}{2Mc}\frac{Mc}{qB} = \frac{1}{2}$$

-



$$\frac{\Delta L_\perp}{L_\perp} \sim \frac{1}{2}$$

-

Thus, applying a magnetic field in the z-direction for a time $> \Delta t$ allows one to resolve the different Zeeman split levels, and hence to measure the z-component of the angular momentum. However, such a measurement necessarily perturbs L_x and L_y, consistent with the uncertainty relation

$$\Delta L_x \, \Delta L_y \geq \frac{\hbar}{2} \left| \langle L_z \rangle \right| .$$

Intrinsic magnetic moment

- There is also a magnetic moment associated with the spin of the electron. However, because $\vec{S} \neq \vec{r} \times \vec{p}$, the derivation $\vec{\mu} \neq -\frac{e}{2mc}\vec{S}$ does not work. Instead,

- $$\vec{\mu} = g\left(-\frac{e}{2mc}\right)\vec{S},$$

  where $g \simeq 2$ (this factor comes from relativistic quantum mechanics, and is one of the most precisely known quantities in the physical sciences).

- The Zeeman effect for the spin

is thus (for $\vec{B} = B\hat{z}$ = const.)

$$-\vec{\mu}\cdot\vec{B} = \frac{geB}{2MC} S_z = \pm \frac{g}{2}\frac{e\hbar}{2MC} B$$

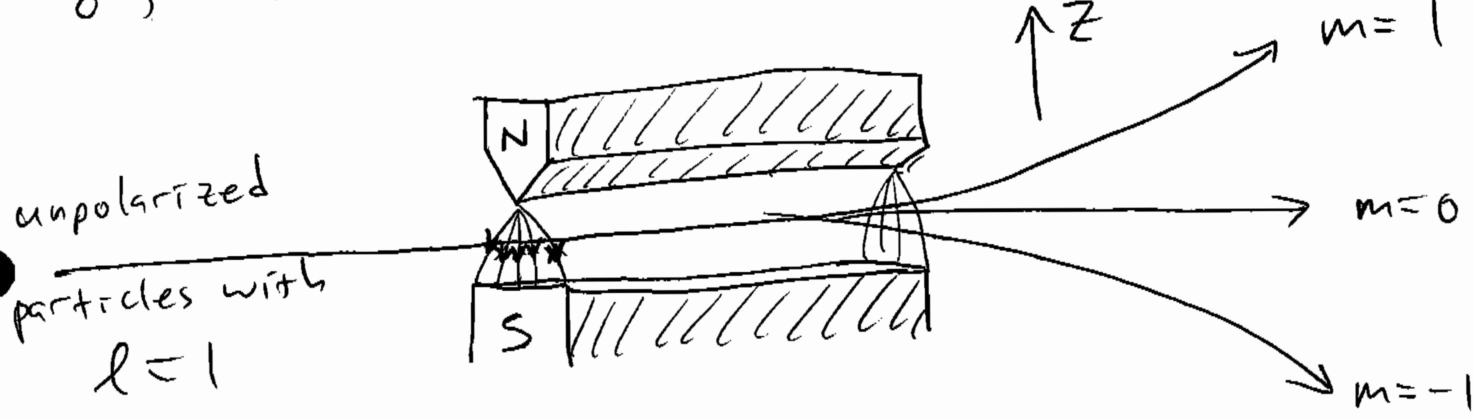
$$= \pm \frac{g}{2} \mu_B B$$

Stern-Gerlach experiment

In an inhomogeneous magnetic field, there is not only a torque, but also a force on a magnetic moment

$$\vec{F} = \nabla(\vec{\mu}\cdot\vec{B}).$$

This force can be used to separate out the different m-components of a beam of particles



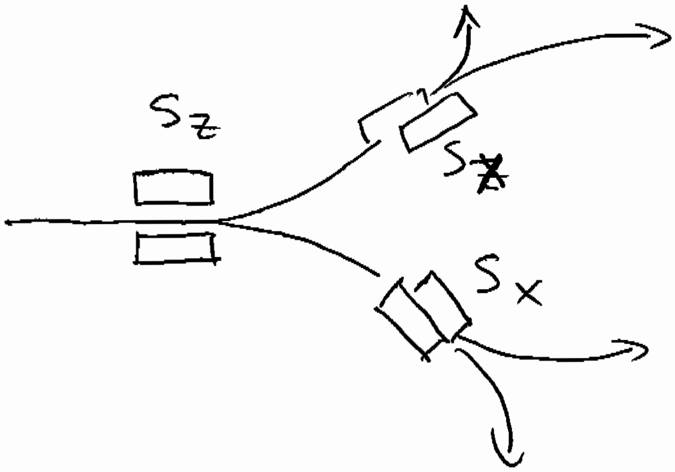
For an unpolarized beam of particles, the # of components in ~~the~~ the beam downstream of the magnet determines the total angular momentum quantum #: $N = 2\ell + 1$.

For an individual particle, the deflection represents a measurement (determination) of the z-component of the angular momentum.

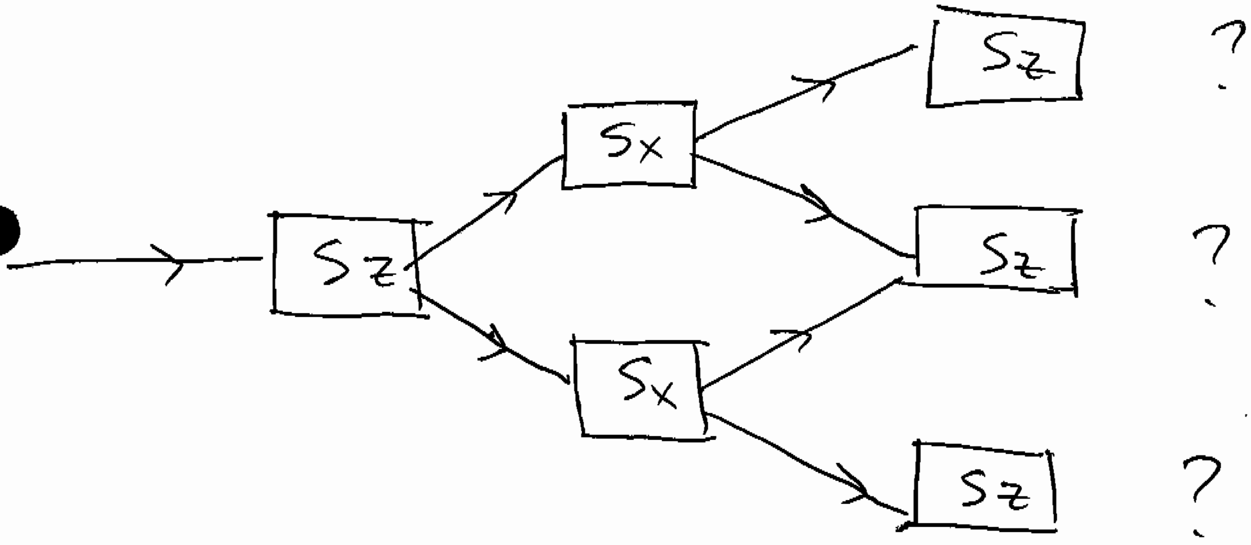
Let's focus on the simplest case, $s = 1/2$. It would be difficult to do the experiment with a free electron, because the beam would be bent and dispersed by the magnetic field, due to the Lorentz force. But for a neutral particle, such as a hydrogen atom, the charge of the electron is balanced by that of the proton, but the magnetic moment is not since

$$\mu_B = \frac{e\hbar}{2m_e c} \gg \mu_p \sim \frac{e\hbar}{2m_p c}$$

Q: What happens if we follow a measurement of S_z by a measurement of S_x?



Each eigenstate of S_z is an equal superposition of S_x eigenstates.



Schematic of triple measurement.
