Fermi National Accelerator Laboratory, P.O. Box 500, Batavia IL 60510

I provide a pedagogical introduction to supersymmetry. The level of discussion is aimed at
readers who are familiar with the Standard Model and quantum field theory, but who have
had little or no prior exposure to supersymmetry. Topics covered include: motivations for
supersymmetry, the construction of supersymmetric Lagrangians, supersymmetry-breaking
interactions, the Minimal Supersymmetric Standard Model (MSSM), $R$-parity and its con-
sequences, the origins of supersymmetry breaking, the mass spectrum of the MSSM, decays
of supersymmetric particles, experimental signals for supersymmetry, and some extensions
of the minimal framework.

1 Introduction

The Standard Model of high-energy physics, augmented by neutrino masses, provides a remarkably successful description of presently known phenomena. The experimental frontier has advanced into the TeV range with no unambiguous hints of additional structure. Still, it seems clear that the Standard Model is a work in progress and will have to be extended to describe physics at higher energies. Certainly, a new framework will be required at the reduced Planck scale $M_P = (8\pi G_{\text{Newton}})^{-1/2} = 2.4 \times 10^{18}$ GeV, where quantum gravitational effects become important. Based only on a proper respect for the power of Nature to surprise us, it seems nearly as obvious that new physics exists in the 16 orders of magnitude in energy between the presently explored territory near the electroweak scale, $M_W$, and the Planck scale.

The mere fact that the ratio $M_P/M_W$ is so huge is already a powerful clue to the character of physics beyond the Standard Model, because of the infamous “hierarchy problem”. This is not really a difficulty with the Standard Model itself, but rather a disturbing sensitivity of the Higgs potential to new physics in almost any imaginable extension of the Standard Model. The electrically neutral part of the Standard Model Higgs field is a complex scalar $H$ with a classical potential

$$V = m_H^2 |H|^2 + \lambda |H|^4.$$  

(1.1)
Figure 1.1: One-loop quantum corrections to the Higgs squared mass parameter $m^2_H$, due to (a) a Dirac fermion $f$, and (b) a scalar $S$.

The Standard Model requires a non-vanishing vacuum expectation value (VEV) for $H$ at the minimum of the potential. This will occur if $\lambda > 0$ and $m^2_H < 0$, resulting in $\langle H \rangle = \sqrt{-m^2_H/2\lambda}$. Since we know experimentally that $\langle H \rangle$ is approximately 174 GeV, from measurements of the properties of the weak interactions, it must be that $m^2_H$ is very roughly of order $-(100 \text{ GeV})^2$. The problem is that $m^2_H$ receives enormous quantum corrections from the virtual effects of every particle that couples, directly or indirectly, to the Higgs field.

For example, in Figure 1.1a we have a correction to $m^2_H$ from a loop containing a Dirac fermion $f$ with mass $m_f$. If the Higgs field couples to $f$ with a term in the Lagrangian $-\lambda f H f$, then the Feynman diagram in Figure 1.1a yields a correction

$$\Delta m^2_H = -\frac{|\lambda_f|^2}{8\pi^2} \Lambda^2_{\text{UV}} + \ldots$$

(1.2)

Here $\Lambda_{\text{UV}}$ is an ultraviolet momentum cutoff used to regulate the loop integral; it should be interpreted as at least the energy scale at which new physics enters to alter the high-energy behavior of the theory. The ellipses represent terms proportional to $m^2_f$, which grow at most logarithmically with $\Lambda_{\text{UV}}$ (and actually differ for the real and imaginary parts of $H$). Each of the leptons and quarks of the Standard Model can play the role of $f$; for quarks, eq. (1.2) should be multiplied by 3 to account for color. The largest correction comes when $f$ is the top quark with $\lambda_f \approx 1$. The problem is that if $\Lambda_{\text{UV}}$ is of order $M_P$, say, then this quantum correction to $m^2_H$ is some 30 orders of magnitude larger than the required value of $m^2_H \sim -(100 \text{ GeV})^2$. This is only directly a problem for corrections to the Higgs scalar boson squared mass, because quantum corrections to fermion and gauge boson masses do not have the direct quadratic sensitivity to $\Lambda_{\text{UV}}$ found in eq. (1.2). However, the quarks and leptons and the electroweak gauge bosons $Z^0, W^\pm$ of the Standard Model all obtain masses from $\langle H \rangle$, so that the entire mass spectrum of the Standard Model is directly or indirectly sensitive to the cutoff $\Lambda_{\text{UV}}$.

One could imagine that the solution is to simply pick a $\Lambda_{\text{UV}}$ that is not too large. But then one still must concoct some new physics at the scale $\Lambda_{\text{UV}}$ that not only alters the propagators in the loop, but actually cuts off the loop integral. This is not easy to do in a theory whose Lagrangian does not contain more than two derivatives, and higher-derivative theories generally suffer from a failure of either unitarity or causality. In string theories, loop integrals are nevertheless cut off at high Euclidean momentum $p$ by factors $e^{-p^2/\Lambda^2_{\text{UV}}}$. However, then $\Lambda_{\text{UV}}$ is a string scale that is usually thought to be not very far below $M_P$. Furthermore, there are contributions similar to eq. (1.2) from the virtual effects of any arbitrarily heavy particles that might exist, and these involve the masses of the heavy particles, not just the cutoff.

For example, suppose there exists a heavy complex scalar particle $S$ with mass $m_S$ that couples to the Higgs with a Lagrangian term $-\lambda_S |H|^2 |S|^2$. Then the Feynman diagram in Figure 1.1b gives a correction

$$\Delta m^2_H = \frac{\lambda_S}{16\pi^2} \left[ \Lambda^2_{\text{UV}} - 2m^2_S \ln(\Lambda_{\text{UV}}/m_S) + \ldots \right].$$

(1.3)

Some recent attacks on the hierarchy problem, not reviewed here, are based on the proposition that the ultimate cutoff scale is actually close to the electroweak scale, rather than the apparent Planck scale.
If one rejects the possibility of a physical interpretation of $\Lambda_{UV}$ and uses dimensional regularization on the loop integral instead of a momentum cutoff, then there will be no $\Lambda_{UV}^2$ piece. However, even then the term proportional to $m_F^2$ cannot be eliminated without the physically unjustifiable tuning of a counter-term specifically for that purpose. So $m_H^2$ is sensitive to the masses of the heaviest particles that $H$ couples to; if $m_S$ is very large, its effects on the Standard Model do not decouple, but instead make it difficult to understand why $m_H^2$ is so small.

This problem arises even if there is no direct coupling between the Standard Model Higgs boson and the unknown heavy particles. For example, suppose there exists a heavy fermion $F$ that, unlike the quarks and leptons of the Standard Model, has vector-like quantum numbers and therefore gets a large mass $m_F$ without coupling to the Higgs field. [In other words, an arbitrarily large mass term of the form $m_F^2 F \overline{F}$ is not forbidden by any symmetry, including weak isospin SU(2)$_L$.] In that case, no diagram like Figure 1.1a exists for $F$. Nevertheless there will be a correction to $m_H^2$ as long as $F$ shares some gauge interactions with the Standard Model Higgs field; these may be the familiar electroweak interactions, or some unknown gauge forces that are broken at a very high energy scale inaccessible to experiment. In either case, the two-loop Feynman diagrams in Figure 1.2 yield a correction

$$\Delta m_H^2 = C_H T_F \left( \frac{g^2}{16\pi^2} \right)^2 \left[ a\Lambda_{UV}^2 + 24m_F^2 \ln(\Lambda_{UV}/m_F) + \ldots \right], \quad (1.4)$$

where $C_H$ and $T_F$ are group theory factors of order 1, and $g$ is the appropriate gauge coupling. The coefficient $a$ depends on the method used to cut off the momentum integrals. It does not arise at all if one uses dimensional regularization, but the $m_F^2$ contribution is always present with the given coefficient. The numerical factor $(g^2/16\pi^2)^2$ may be quite small (of order $10^{-5}$ for electroweak interactions), but the important point is that these contributions to $\Delta m_H^2$ are sensitive both to the largest masses and to the ultraviolet cutoff in the theory, presumably of order $M_P$. The “natural” squared mass of a fundamental Higgs scalar, including quantum corrections, therefore seems to be more like $M_P^2$ than the experimentally favored value! Even very indirect contributions from Feynman diagrams with three or more loops can give unacceptably large contributions to $\Delta m_H^2$. The argument above applies not just for heavy particles, but for arbitrary high-scale physical phenomena such as condensates or additional compactified dimensions.

It could be that there is no fundamental Higgs boson, as in technicolor models, top-quark condensate models, and models in which the Higgs boson is composite. Or it could be that the ultimate ultraviolet cutoff scale is much lower than the Planck scale. These ideas are certainly worth exploring, although they often present difficulties in their simplest forms. But, if the Higgs boson is a fundamental particle, and there really is physics far above the electroweak scale, then we have two remaining options: either we must make the rather bizarre assumption that there do not exist any high-mass particles or effects that couple (even indirectly or extremely weakly) to the Higgs scalar field, or else some striking cancellation is needed between the various contributions to $\Delta m_H^2$.

---

1Specifically, $C_H$ is the quadratic Casimir invariant of $H$, and $T_F$ is the Dynkin index of $F$ in a normalization such that $T_F = 1$ for a Dirac fermion (or two Weyl fermions) in a fundamental representation of SU($n$).
The systematic cancellation of the dangerous contributions to $\Delta m^2_H$ can only be brought about by the type of conspiracy that is better known to physicists as a symmetry. Comparing eqs. (1.2) and (1.3) strongly suggests that the new symmetry ought to relate fermions and bosons, because of the relative minus sign between fermion loop and boson loop contributions to $\Delta m^2_H$. (Note that $\lambda_S$ must be positive if the scalar potential is to be bounded from below.) If each of the quarks and leptons of the Standard Model is accompanied by two complex scalars with $\lambda_S = |\lambda_f|^2$, then the $\Lambda^2_{UV}$ contributions of Figures 1.1a and 1.1b will neatly cancel [3]. Clearly, more restrictions on the theory will be necessary to ensure that this success persists to higher orders, so that, for example, the contributions in Figure 1.2 and eq. (1.4) from a very heavy fermion are canceled by the two-loop effects of some very heavy bosons. Fortunately, the cancellation of all such contributions to scalar masses is not only possible, but is actually unavoidable, once we merely assume that there exists a symmetry relating fermions and bosons, called a supersymmetry.

A supersymmetry transformation turns a bosonic state into a fermionic state, and vice versa. The operator $Q$ that generates such transformations must be an anticommuting spinor, with

$$Q|\text{Boson}\rangle = |\text{Fermion}\rangle, \quad Q|\text{Fermion}\rangle = |\text{Boson}\rangle. \quad (1.5)$$

Spinors are intrinsically complex objects, so $Q^\dagger$ (the hermitian conjugate of $Q$) is also a symmetry generator. Because $Q$ and $Q^\dagger$ are fermionic operators, they carry spin angular momentum 1/2, so it is clear that supersymmetry must be a spacetime symmetry. The possible forms for such symmetries in an interacting quantum field theory are highly restricted by the Haag-Lopuszanski-Sohnius extension of the Coleman-Mandula theorem [4]. For realistic theories that, like the Standard Model, have chiral fermions (i.e., fermions whose left- and right-handed pieces transform differently under the gauge group) and thus the possibility of parity-violating interactions, this theorem implies that the generators $Q$ and $Q^\dagger$ must satisfy an algebra of anticommutation and commutation relations with the schematic form

$$\{Q, Q^\dagger\} = P^\mu, \quad (1.6)$$

$$\{Q, Q\} = \{Q^\dagger, Q^\dagger\} = 0, \quad (1.7)$$

$$[P^\mu, Q] = [P^\mu, Q^\dagger] = 0, \quad (1.8)$$

where $P^\mu$ is the four-momentum generator of spacetime translations. Here we have ruthlessly suppressed the spinor indices on $Q$ and $Q^\dagger$; after developing some notation we will, in section 3.1, derive the precise version of eqs. (1.6) - (1.8) with indices restored. In the meantime, we simply note that the appearance of $P^\mu$ on the right-hand side of eq. (1.6) is unsurprising, since it transforms under Lorentz boosts and rotations as a spin-1 object while $Q$ and $Q^\dagger$ on the left-hand side each transform as spin-1/2 objects.

The single-particle states of a supersymmetric theory fall into irreducible representations of the supersymmetry algebra, called supermultiplets. Each supermultiplet contains both fermion and boson states, which are commonly known as superpartners of each other. By definition, if $|\Omega\rangle$ and $|\Omega'\rangle$ are members of the same supermultiplet, then $|\Omega'\rangle$ is proportional to some combination of $Q$ and $Q^\dagger$ operators acting on $|\Omega\rangle$, up to a spacetime translation or rotation. The squared-mass operator $-P^2$ commutes with the operators $Q$, $Q^\dagger$, and with all spacetime rotation and translation operators, so it follows immediately that particles inhabiting the same irreducible supermultiplet must have equal eigenvalues of $-P^2$, and therefore equal masses.

The supersymmetry generators $Q, Q^\dagger$ also commute with the generators of gauge transformations. Therefore particles in the same supermultiplet must also be in the same representation of the gauge group, and so must have the same electric charges, weak isospin, and color degrees of freedom.

Each supermultiplet contains an equal number of fermion and boson degrees of freedom. To prove this, consider the operator $(-1)^{2s}$ where $s$ is the spin angular momentum. By the spin-statistics theorem, this operator has eigenvalue +1 acting on a bosonic state and eigenvalue −1 acting on a
fermionic state. Any fermionic operator will turn a bosonic state into a fermionic state and vice versa. Therefore \((-1)^{2s}\) must anticommute with every fermionic operator in the theory, and in particular with \(Q\) and \(Q^\dagger\). Now, within a given supermultiplet, consider the subspace of states \(|i\rangle\) with the same eigenvalue \(p^\mu\) of the four-momentum operator \(P^\mu\). In view of eq. (1.8), any combination of \(Q\) or \(Q^\dagger\) acting on \(|i\rangle\) must give another state \(|j\rangle\) with the same four-momentum eigenvalue. Therefore one has a completeness relation \(\sum_i |i\rangle\langle i| = 1\) within this subspace of states. Now one can take a trace over all such states of the operator \((-1)^{2s}P^\mu\) (including each spin helicity state separately):

\[
\sum_i \langle i|(-1)^{2s}P^\mu|i\rangle = \sum_i \langle i|(-1)^{2s}QQ^\dagger|i\rangle + \sum_i \langle i|(-1)^{2s}Q^\dagger Q|i\rangle = \sum_i \langle i|(-1)^{2s}QQ^\dagger|i\rangle + \sum_j \langle j|Q(-1)^{2s}Q^\dagger|j\rangle = \sum_i \langle i|(-1)^{2s}QQ^\dagger|i\rangle - \sum_j \langle j|(-1)^{2s}QQ^\dagger|j\rangle = 0.
\]

The first equality follows from the supersymmetry algebra relation eq. (1.6); the second and third from use of the completeness relation; and the fourth from the fact that \((-1)^{2s}\) must anticommute with \(Q\). Now \(\sum_i \langle i|(-1)^{2s}P^\mu|i\rangle = p^\mu \text{Tr}[(-1)^{2s}]\) is just proportional to the number of bosonic degrees of freedom \(n_B\) minus the number of fermionic degrees of freedom \(n_F\) in the trace, so that

\[
n_B = n_F
\]

must hold for a given \(p^\mu \neq 0\) in each supermultiplet.

The simplest possibility for a supermultiplet consistent with eq. (1.10) has a single Weyl fermion (with two spin helicity states, so \(n_F = 2\)) and two real scalars (each with \(n_B = 1\)). It is natural to assemble the two real scalar degrees of freedom into a complex scalar field; as we will see below this provides for convenient formulations of the supersymmetry algebra, Feynman rules, supersymmetry-violating effects, etc. This combination of a two-component Weyl fermion and a complex scalar field is called a chiral or matter or scalar supermultiplet.

The next-simplest possibility for a supermultiplet contains a spin-1 vector boson. If the theory is to be renormalizable, this must be a gauge boson that is massless, at least before the gauge symmetry is spontaneously broken. A massless spin-1 boson has two helicity states, so the number of bosonic degrees of freedom is \(n_B = 2\). Its superpartner is therefore a massless spin-1/2 Weyl fermion, again with two helicity states, so \(n_F = 2\). (If one tried to use a massless spin-3/2 fermion instead, the theory would not be renormalizable.) Gauge bosons must transform as the adjoint representation of the gauge group, so their fermionic partners, called gauginos, must also. Since the adjoint representation of a gauge group is always its own conjugate, the gaugino fermions must have the same gauge transformation properties for left-handed and for right-handed components. Such a combination of spin-1/2 gauginos and spin-1 gauge bosons is called a gauge or vector supermultiplet.

If we include gravity, then the spin-2 graviton (with 2 helicity states, so \(n_B = 2\)) has a spin-3/2 superpartner called the gravitino. The gravitino would be massless if supersymmetry were unbroken, and so it has \(n_F = 2\) helicity states.

There are other possible combinations of particles with spins that can satisfy eq. (1.10). However, these are always reducible to combinations\(^5\) of chiral and gauge supermultiplets if they have renormal-

\(^5\)For example, if a gauge symmetry were to spontaneously break without breaking supersymmetry, then a massless vector supermultiplet would “eat” a chiral supermultiplet, resulting in a massive vector supermultiplet with physical degrees of freedom consisting of a massive vector \((n_B = 3)\), a massive Dirac fermion formed from the gaugino and the chiral fermion \((n_F = 4)\), and a real scalar \((n_B = 1)\).
izable interactions, except in certain theories with “extended” supersymmetry. Theories with extended supersymmetry have more than one distinct copy of the supersymmetry generators $Q, Q^\dagger$. Such models are mathematically amusing, but evidently do not have any phenomenological prospects. The reason is that extended supersymmetry in four-dimensional field theories cannot allow for chiral fermions or parity violation as observed in the Standard Model. So we will not discuss such possibilities further, although extended supersymmetry in higher-dimensional field theories might describe the real world if the extra dimensions are compactified in an appropriate way, and extended supersymmetry in four dimensions provides interesting toy models. The ordinary, non-extended, phenomenologically viable type of supersymmetric model is sometimes called $N = 1$ supersymmetry, with $N$ referring to the number of supersymmetries (the number of distinct copies of $Q, Q^\dagger$).

In a supersymmetric extension of the Standard Model \[5\]-\[7\], each of the known fundamental particles is therefore in either a chiral or gauge supermultiplet, and must have a superpartner with spin differing by $1/2$ unit. The first step in understanding the exciting phenomenological consequences of this prediction is to decide exactly how the known particles fit into supermultiplets, and to give them appropriate names. A crucial observation here is that only chiral supermultiplets can contain fermions whose left-handed parts transform differently under the gauge group than their right-handed parts. All of the Standard Model fermions (the known quarks and leptons) have this property, so they must be members of chiral supermultiplets.\(^6\) The names for the spin-0 partners of the quarks and leptons are constructed by prepending an “s”, for scalar. So, generically they are called squarks and sleptons (short for “scalar quark” and “scalar lepton”), or sometimes sfermions. The left-handed and right-handed pieces of the squarks and sleptons are separate two-component Weyl fermions with different gauge transformation properties in the Standard Model, so each must have its own complex scalar partner. The symbols for the squarks and sleptons are the same as for the corresponding fermion, but with a tilde ($\tilde{}$) used to denote the superpartner of a Standard Model particle. For example, the superpartners of the left-handed and right-handed parts of the electron Dirac field are called left- and right-handed selectrons, and are denoted $\tilde{e}_L$ and $\tilde{e}_R$. It is important to keep in mind that the “handedness” here does not refer to the helicity of the selectrons (they are spin-0 particles) but to that of their superpartners. A similar nomenclature applies for smuons and staus: $\tilde{\mu}_L, \tilde{\mu}_R, \tilde{\tau}_L, \tilde{\tau}_R$. The Standard Model neutrinos (neglecting their very small masses) are always left-handed, so the sneutrinos are denoted generically by $\tilde{\nu}$, with a possible subscript indicating which lepton flavor they carry: $\tilde{\nu}_e, \tilde{\nu}_\mu, \tilde{\nu}_\tau$. Finally, a complete list of the squarks is $\tilde{q}_L, \tilde{q}_R$ with $q = u, d, s, c, b, t$. The gauge interactions of each of these squark and slepton fields are the same as for the corresponding Standard Model fermions; for instance, the left-handed squarks $\tilde{u}_L$ and $\tilde{d}_L$ couple to the $W$ boson, while $\tilde{u}_R$ and $\tilde{d}_R$ do not.

It seems clear that the Higgs scalar boson must reside in a chiral supermultiplet, since it has spin 0. Actually, it turns out that just one chiral supermultiplet is not enough. One reason for this is that if there were only one Higgs chiral supermultiplet, the electroweak gauge symmetry would suffer a gauge anomaly, and would be inconsistent as a quantum theory. This is because the conditions for cancellation of gauge anomalies include $\text{Tr}[T^2_3 Y] = \text{Tr}[Y^3] = 0$, where $T_3$ and $Y$ are the third component of weak isospin and the weak hypercharge, respectively, in a normalization where the ordinary electric charge is $Q_{\text{EM}} = T_3 + Y$. The traces run over all of the left-handed Weyl fermionic degrees of freedom in the theory. In the Standard Model, these conditions are already satisfied, somewhat miraculously, by the known quarks and leptons. Now, a fermionic partner of a Higgs chiral supermultiplet must be a weak isodoublet with weak hypercharge $Y = 1/2$ or $Y = -1/2$. In either case alone, such a fermion will make a non-zero contribution to the traces and spoil the anomaly cancellation. This can be avoided if there are two Higgs supermultiplets, one with each of $Y = \pm 1/2$, so that the total contribution to the anomaly traces from the two fermionic members of the Higgs chiral supermultiplets vanishes by cancellation. As we will see in section 5.1 both of these are also necessary for another

\(^6\)In particular, one cannot attempt to make a spin-1/2 neutrino be the superpartner of the spin-1 photon; the neutrino is in a doublet, and the photon is neutral, under weak isospin.
Table 1.1: Chiral supermultiplets in the Minimal Supersymmetric Standard Model. The spin-0 fields are complex scalars, and the spin-1/2 fields are left-handed two-component Weyl fermions.

completely different reason: because of the structure of supersymmetric theories, only a $Y = 1/2$ Higgs chiral supermultiplet can have the Yukawa couplings necessary to give masses to charge +2/3 up-type quarks (up, charm, top), and only a $Y = -1/2$ Higgs can have the Yukawa couplings necessary to give masses to charge −1/3 down-type quarks (down, strange, bottom) and to the charged leptons. We will call the $SU(2)_L$-doublet complex scalar fields with $Y = 1/2$ and $Y = -1/2$ by the names $H_u$ and $H_d$, respectively.† The weak isospin components of $H_u$ with $T_3 = (1/2, -1/2)$ have electric charges 1, 0 respectively, and are denoted $(H_u^+, H_u^0)$. Similarly, the $SU(2)_L$-doublet complex scalar $H_d$ has $T_3 = (1/2, -1/2)$ components $(H_d^0, H_d^-)$. The neutral scalar that corresponds to the physical Standard Model Higgs boson is in a linear combination of $H_u^0$ and $H_d^0$; we will discuss this further in section 7.1.

The generic nomenclature for a spin-1/2 superpartner is to append “-ino” to the name of the Standard Model particle, so the fermionic partners of the Higgs scalars are called higgsinos. They are denoted by $\tilde H_u, \tilde H_d$ for the $SU(2)_L$-doublet left-handed Weyl spinor fields, with weak isospin components $\tilde H_u^+, \tilde H_0^u$ and $\tilde H_d^0, \tilde H_d^-$. We have now found all of the chiral supermultiplets of a minimal phenomenologically viable extension of the Standard Model. They are summarized in Table 1.1, classified according to their transformation properties under the Standard Model gauge group $SU(3)_C \times SU(2)_L \times U(1)_Y$, which combines $u_L, d_L$ and $\nu, e_L$ degrees of freedom into $SU(2)_L$ doublets. Here we follow a standard convention, that all chiral supermultiplets are defined in terms of left-handed Weyl spinors, so that the conjugates of the right-handed quarks and leptons (and their superpartners) appear in Table 1.1. This protocol for defining chiral supermultiplets turns out to be very useful for constructing supersymmetric Lagrangians, as we will see in section 3. It is also useful to have a symbol for each of the chiral supermultiplets as a whole; these are indicated in the second column of Table 1.1. Thus, for example, $Q$ stands for the $SU(2)_L$-doublet chiral supermultiplet containing $\bar u_L, u_L$ (with weak isospin component $T_3 = 1/2$), and $\bar d_L, d_L$ (with $T_3 = -1/2$), while $\pi$ stands for the $SU(2)_L$-singlet supermultiplet containing $\bar u_R, u_R^\dagger$. There are three families for each of the quark and lepton supermultiplets, Table 1.1 lists the first-family representatives. A family index $i = 1, 2, 3$ can be affixed to the chiral supermultiplet names ($Q_i, \bar \pi_i, \ldots$) when needed, for example $(\bar \nu_i, \bar e_L, \nu_i, e_L)$. The bar on $\pi, \bar d, \bar \tau$ fields is part of the name, and does not denote any kind of conjugation.

The Higgs chiral supermultiplet $H_d$ (containing $H_d^0, H_d^-, \tilde H_d^0, \tilde H_d^-$) has exactly the same Standard Model gauge quantum numbers as the left-handed sleptons and leptons $L_i$, for example $(\bar \nu, \bar e_L, \nu, e_L)$. Naively, one might therefore suppose that we could have been more economical in our assignment

† Other notations in the literature have $H_1, H_2$ or $H, \bar H$ instead of $H_u, H_d$. The notation used here has the virtue of making it easy to remember which Higgs VEVs gives masses to which type of quarks.
by taking a neutrino and a Higgs scalar to be superpartners, instead of putting them in separate supermultiplets. This would amount to the proposal that the Higgs boson and a sneutrino should be the same particle. This attempt played a key role in some of the first attempts to connect supersymmetry to phenomenology [5], but it is now known to not work. Even ignoring the anomaly cancellation problem mentioned above, many insoluble phenomenological problems would result, including lepton-number non-conservation and a mass for at least one of the neutrinos in gross violation of experimental bounds. Therefore, all of the superpartners of Standard Model particles are really new particles, and cannot be identified with some other Standard Model state.

The vector bosons of the Standard Model clearly must reside in gauge supermultiplets. Their fermionic superpartners are generically referred to as gauginos. The $SU(3)_C$ color gauge interactions of QCD are mediated by the gluon, whose spin-1/2 color-octet supersymmetric partner is the gluino. As usual, a tilde is used to denote the supersymmetric partner of a Standard Model state, so the symbols for the gluon and gluino are $g$ and \( \tilde{g} \) respectively. The electroweak gauge symmetry $SU(2)_L \times U(1)_Y$ is associated with spin-1 gauge bosons $W^+, W^0, W^-$ and $B^0$, with spin-1/2 superpartners $\tilde{W}^+, \tilde{W}^0, \tilde{W}^-$ and $\tilde{B}^0$, called winos and bino. After electroweak symmetry breaking, the $W^0, B^0$ gauge eigenstates mix to give mass eigenstates $Z^0$ and $\gamma$. The corresponding gaugino mixtures of $\tilde{W}^0$ and $\tilde{B}^0$ are called zino ($\tilde{Z}^0$) and photino ($\tilde{\gamma}$); if supersymmetry were unbroken, they would be mass eigenstates with masses $m_Z$ and 0. Table 1.2 summarizes the gauge supermultiplets of a minimal supersymmetric extension of the Standard Model.

The chiral and gauge supermultiplets in Tables 1.1 and 1.2 make up the particle content of the Minimal Supersymmetric Standard Model (MSSM). The most obvious and interesting feature of this theory is that none of the superpartners of the Standard Model particles has been discovered as of this writing. If supersymmetry were unbroken, then there would have to be selectrons $\tilde{e}_L$ and $\tilde{e}_R$ with masses exactly equal to $m_e = 0.511\ldots$ MeV. A similar statement applies to each of the other sleptons and squarks, and there would also have to be a massless gluino and photino. These particles would have been extraordinarily easy to detect long ago. Clearly, therefore, supersymmetry is a broken symmetry in the vacuum state chosen by Nature.

An important clue as to the nature of supersymmetry breaking can be obtained by returning to the motivation provided by the hierarchy problem. Supersymmetry forced us to introduce two complex scalar fields for each Standard Model Dirac fermion, which is just what is needed to enable a cancellation of the quadratically divergent (\( \Lambda_{UV}^2 \)) pieces of eqs. (1.2) and (1.3). This sort of cancellation also requires that the associated dimensionless couplings should be related (for example $\lambda_S = |\lambda_f|^2$). The necessary relationships between couplings indeed occur in unbroken supersymmetry, as we will see in section 3. In fact, unbroken supersymmetry guarantees that the quadratic divergences in scalar squared masses must vanish to all orders in perturbation theory.‡ Now, if broken supersymmetry is still to provide a solution to the hierarchy problem even in the presence of supersymmetry breaking, then

---

\[ \Lambda_{UV}^2 \]

‡A simple way to understand this is to recall that unbroken supersymmetry requires the degeneracy of scalar and fermion masses. Radiative corrections to fermion masses are known to diverge at most logarithmically in any renormalizable field theory, so the same must be true for scalar masses in unbroken supersymmetry.
the relationships between dimensionless couplings that hold in an unbroken supersymmetric theory must be maintained. Otherwise, there would be quadratically divergent radiative corrections to the Higgs scalar masses of the form

\[ \Delta m^2_H = \frac{1}{8\pi^2} (\lambda_S - |\lambda_f|^2) \Lambda_{UV}^2 + \ldots \]  

We are therefore led to consider “soft” supersymmetry breaking. This means that the effective Lagrangian of the MSSM can be written in the form

\[ \mathcal{L} = \mathcal{L}_{SUSY} + \mathcal{L}_{soft}, \]  

where \( \mathcal{L}_{SUSY} \) contains all of the gauge and Yukawa interactions and preserves supersymmetry invariance, and \( \mathcal{L}_{soft} \) violates supersymmetry but contains only mass terms and coupling parameters with positive mass dimension. Without further justification, soft supersymmetry breaking might seem like a rather arbitrary requirement. Fortunately, we will see in section that theoretical models for supersymmetry breaking do indeed yield effective Lagrangians with just such terms for \( \mathcal{L}_{soft} \). If the largest mass scale associated with the soft terms is denoted \( m_{soft} \), then the additional non-supersymmetric corrections to the Higgs scalar squared mass must vanish in the \( m_{soft} \to 0 \) limit, so by dimensional analysis they cannot be proportional to \( \Lambda_{UV}^2 \). More generally, these models maintain the cancellation of quadratically divergent terms in the radiative corrections of all scalar masses, to all orders in perturbation theory. The corrections also cannot go like \( \Delta m^2_H \sim m_{soft} \Lambda_{UV} \), because in general the loop momentum integrals always diverge either quadratically or logarithmically, not linearly, as \( \Lambda_{UV} \to \infty \). So they must be of the form

\[ \Delta m^2_H = m_{soft}^2 \left[ \frac{\lambda}{16\pi^2} \ln(\Lambda_{UV}/m_{soft}) + \ldots \right]. \]  

Here \( \lambda \) is schematic for various dimensionless couplings, and the ellipses stand both for terms that are independent of \( \Lambda_{UV} \) and for higher loop corrections (which depend on \( \Lambda_{UV} \) through powers of logarithms).

Because the mass splittings between the known Standard Model particles and their superpartners are just determined by the parameters \( m_{soft} \) appearing in \( \mathcal{L}_{soft} \), eq. (1.13) tells us that the superpartner masses cannot be too huge. Otherwise, we would lose our successful cure for the hierarchy problem, since the \( m_{soft}^2 \) corrections to the Higgs scalar squared mass parameter would be unnaturally large compared to the square of the electroweak breaking scale of 174 GeV. The top and bottom squarks and the winos and bino give especially large contributions to \( \Delta m^2_{H_u} \) and \( \Delta m^2_{H_d} \), but the gluino mass and all the other squark and slepton masses also feed in indirectly, through radiative corrections to the top and bottom squark masses. Furthermore, in most viable models of supersymmetry breaking that are not unduly contrived, the superpartner masses do not differ from each other by more than about an order of magnitude. Using \( \Lambda_{UV} \sim M_P \) and \( \lambda \sim 1 \) in eq. (1.13), one finds that \( m_{soft} \), and therefore the masses of at least the lightest few superpartners, should be at the most about 1 TeV or so, in order for the MSSM scalar potential to provide a Higgs VEV resulting in \( m_W, m_Z = 80.4, 91.2 \) GeV without miraculous cancellations. This is the best reason for the optimism among many theorists that supersymmetry will be discovered at the Fermilab Tevatron or the CERN Large Hadron Collider, and can be studied at a future \( e^+e^- \) linear collider.

However, it should be noted that the hierarchy problem was not the historical motivation for the development of supersymmetry in the early 1970’s. The supersymmetry algebra and supersymmetric field theories were originally concocted independently in various disguises bearing little resemblance to the MSSM. It is quite impressive that a theory developed for quite different reasons, including purely aesthetic ones, can later be found to provide a solution for the hierarchy problem.
One might also wonder whether there is any good reason why all of the superpartners of the Standard Model particles should be heavy enough to have avoided discovery so far. There is. All of the particles in the MSSM that have been found so far have something in common; they would necessarily be massless in the absence of electroweak symmetry breaking. In particular, the masses of the $W^\pm$, $Z^0$ bosons and all quarks and leptons are equal to dimensionless coupling constants times the Higgs VEV $\sim 174$ GeV, while the photon and gluon are required to be massless by electromagnetic and QCD gauge invariance. Conversely, all of the undiscovered particles in the MSSM have exactly the opposite property; each of them can have a Lagrangian mass term in the absence of electroweak symmetry breaking. For the squarks, sleptons, and Higgs scalars this follows from a general property of complex scalar fields that a mass term $m^2|\phi|^2$ is always allowed by all gauge symmetries. For the higgsinos and gauginos, it follows from the fact that they are fermions in a real representation of the gauge group. So, from the point of view of the MSSM, the discovery of the top quark in 1995 marked a quite natural milestone; the already-discovered particles are precisely those that had to be light, based on the principle of electroweak gauge symmetry. There is a single exception: one neutral Higgs scalar boson should be lighter than about 135 GeV if the minimal version of supersymmetry is correct, for reasons to be discussed in section 7.1. In non-minimal models that do not have extreme fine tuning of parameters, and that remain perturbative up to the scale of apparent gauge coupling unification, the lightest Higgs scalar boson can have a mass up to about 150 GeV.

An important feature of the MSSM is that the superpartners listed in Tables 1.1 and 1.2 are not necessarily the mass eigenstates of the theory. This is because after electroweak symmetry breaking and supersymmetry breaking effects are included, there can be mixing between the electroweak gauginos and the higgsinos, and within the various sets of squarks and sleptons and Higgs scalars that have the same electric charge. The lone exception is the gluino, which is a color octet fermion and therefore does not have the appropriate quantum numbers to mix with any other particle. The masses and mixings of the superpartners are obviously of paramount importance to experimentalists. It is perhaps slightly less obvious that these phenomenological issues are all quite directly related to one central question that is also the focus of much of the theoretical work in supersymmetry: “How is supersymmetry broken?” The reason for this is that most of what we do not already know about the MSSM has to do with $L_{\text{soft}}$. The structure of supersymmetric Lagrangians allows little arbitrariness, as we will see in section 8. In fact, all of the dimensionless couplings and all but one mass term in the supersymmetric part of the MSSM Lagrangian correspond directly to parameters in the ordinary Standard Model that have already been measured by experiment. For example, we will find out that the supersymmetric coupling of a gluino to a squark and a quark is determined by the QCD coupling constant $\alpha_S$. In contrast, the supersymmetry-breaking part of the Lagrangian contains many unknown parameters and, apparently, a considerable amount of arbitrariness. Each of the mass splittings between Standard Model particles and their superpartners correspond to terms in the MSSM Lagrangian that are purely supersymmetry-breaking in their origin and effect. These soft supersymmetry-breaking terms can also introduce a large number of mixing angles and CP-violating phases not found in the Standard Model. Fortunately, as we will see in section 5.4 there is already strong evidence that the supersymmetry-breaking terms in the MSSM are actually not arbitrary at all. Furthermore, the additional parameters will be measured and constrained as the superpartners are detected. From a theoretical perspective, the challenge is to explain all of these parameters with a predictive model for supersymmetry breaking.

The rest of the discussion is organized as follows. Section 2 provides a list of important notations. In section 3 we will learn how to construct Lagrangians for supersymmetric field theories. Soft supersymmetry-breaking couplings are described in section 4. In section 5 we will apply the preceding general results to the special case of the MSSM, introduce the concept of $R$-parity, and emphasize the importance of the structure of the soft terms. Section 6 outlines some considerations for understanding the origin of supersymmetry breaking, and the consequences of various proposals. In section 7 we will study the mass and mixing angle patterns of the new particles predicted by the MSSM. Their
decay modes are considered in section 8 and some of the qualitative features of experimental signals for supersymmetry are reviewed in section 9. Section 10 describes some sample variations on the standard MSSM picture. The discussion will be lacking in historical accuracy or perspective; the reader is encouraged to consult the many outstanding books [12]-[24], review articles [25]-[48] and the reprint volume [49], which contain a much more consistent guide to the original literature.

2 Interlude: Notations and Conventions

This section specifies my notations and conventions. Four-vector indices are represented by letters from the middle of the Greek alphabet \( \mu, \nu, \rho, \ldots = 0, 1, 2, 3 \). The contravariant four-vector position and momentum of a particle are

\[
x^\mu = (t, \vec{x}), \quad p^\mu = (E, \vec{p}),
\]

while the four-vector derivative is

\[
\partial_\mu = (\partial/\partial t, \vec{\nabla}).
\]

The spacetime metric is

\[
\eta_{\mu\nu} = \text{diag}(-1, +1, +1, +1),
\]

so that \( p^2 = -m^2 \) for an on-shell particle of mass \( m \).

It is overwhelmingly convenient to employ two-component Weyl spinor notation for fermions, rather than four-component Dirac or Majorana spinors. The Lagrangian of the Standard Model (and any supersymmetric extension of it) violates parity; each Dirac fermion has left-handed and right-handed parts with completely different electroweak gauge interactions. If one used four-component spinor notation instead, then there would be clumsy left- and right-handed projection operators

\[
P_L = (1 - \gamma_5)/2, \quad P_R = (1 + \gamma_5)/2
\]

all over the place. The two-component Weyl fermion notation has the advantage of treating fermionic degrees of freedom with different gauge quantum numbers separately from the start, as Nature intended for us to do. But an even better reason for using two-component notation here is that in supersymmetric models the minimal building blocks of matter are chiral supermultiplets, each of which contains a single two-component Weyl fermion. Since two-component fermion notation may be unfamiliar to some readers, I now specify my conventions by showing how they correspond to the four-component spinor language. A four-component Dirac fermion \( \Psi_D \) with mass \( M \) is described by the Lagrangian

\[
\mathcal{L}_{\text{Dirac}} = -i\overline{\Psi}_D \gamma^\mu \partial_\mu \Psi_D - M \overline{\Psi}_D \Psi_D.
\]

For our purposes it is convenient to use the specific representation of the \( 4 \times 4 \) gamma matrices given in \( 2 \times 2 \) blocks by

\[
\begin{pmatrix} 0 & \sigma^\mu \\ \sigma_\mu & 0 \end{pmatrix}, \quad \gamma_5 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},
\]

where

\[
\sigma_0 = \sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \sigma_1 = -\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},
\]

\[
\sigma_2 = -\sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = -\sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.
\]
In this representation, a four-component Dirac spinor is written in terms of 2 two-component, complex, anticommuting objects $\xi_\alpha$ and $(\chi^{\dagger})^{\dot{\alpha}} \equiv \chi_{\dot{\alpha}}$ with two distinct types of spinor indices $\alpha = 1, 2$ and $\dot{\alpha} = 1, 2$:

$$\Psi_D = \begin{pmatrix} \xi_\alpha \\ \chi_{\dot{\alpha}} \end{pmatrix}. \quad (2.8)$$

It follows that

$$\Psi_D^\dagger = \Psi_D^\dagger \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} \chi^\alpha & \xi^{\dagger}_{\dot{\alpha}} \end{pmatrix}. \quad (2.9)$$

Undotted (dotted) indices from the beginning of the Greek alphabet are used for the first (last) two components of a Dirac spinor. The field $\xi$ is called a “left-handed Weyl spinor” and $\chi^{\dagger}$ is a “right-handed Weyl spinor”. The names fit, because

$$P_L \Psi_D = \begin{pmatrix} \xi_\alpha \\ 0 \end{pmatrix}, \quad P_R \Psi_D = \begin{pmatrix} 0 \\ \chi_{\dot{\alpha}} \end{pmatrix}. \quad (2.10)$$

The Hermitian conjugate of any left-handed Weyl spinor is a right-handed Weyl spinor:

$$\psi^{\dagger}_{\dot{\alpha}} \equiv (\psi_\alpha)^\dagger = (\psi^{\dagger})_{\dot{\alpha}}, \quad (2.11)$$

and vice versa:

$$(\psi^{\dagger}_{\dot{\alpha}})^\dagger = \psi^\alpha. \quad (2.12)$$

Therefore, any particular fermionic degrees of freedom can be described equally well using a left-handed Weyl spinor (with an undotted index) or by a right-handed one (with a dotted index). By convention, all names of fermion fields are chosen so that left-handed Weyl spinors do not carry daggers and right-handed Weyl spinors do carry daggers, as in eq. (2.8).

The heights of the dotted and undotted spinor indices are important; for example, comparing eqs. (2.5)–(2.9), we observe that the matrices $(\sigma^\mu)_{\alpha\dot{\alpha}}$ and $(\sigma^\mu)^{\dot{\alpha}\alpha}$ defined by eq. (2.7) carry indices with the heights as indicated. The spinor indices are raised and lowered using the antisymmetric symbol $\epsilon_{12} = -\epsilon_{21} = 1, \epsilon_{11} = \epsilon_{22} = 0$, according to

$$\xi_{\alpha} = \epsilon_{\alpha\beta} \xi^\beta, \quad \xi^{\alpha} = \epsilon^{\alpha\beta} \xi_{\beta}, \quad \chi^\dagger_{\dot{\alpha}} = \epsilon^\dagger_{\dot{\alpha}\dot{\beta}} \chi^\dagger_{\dot{\beta}}, \quad \chi_{\dot{\alpha}} = \epsilon_{\dot{\alpha}\dot{\beta}} \chi_{\dot{\beta}}. \quad (2.13)$$

This is consistent since $\epsilon_{\alpha\beta} \epsilon^{\beta\gamma} = \epsilon^{\gamma\beta} \epsilon_{\beta\alpha} = \delta^\gamma_{\alpha}$ and $\epsilon_{\dot{\alpha}\dot{\beta}} \epsilon^{\dot{\beta}\dot{\gamma}} = \epsilon^{\dot{\gamma}\dot{\beta}} \epsilon_{\dot{\beta}\dot{\alpha}} = \delta^\dot{\gamma}_{\dot{\alpha}}$.

As a convention, repeated spinor indices contracted like

$$\epsilon_{\alpha\alpha} \quad \text{or} \quad \epsilon_{\dot{\alpha}\dot{\alpha}} \quad (2.14)$$

can be suppressed. In particular,

$$\xi \chi \equiv \xi^\alpha \chi_{\alpha} = \xi^\alpha \epsilon_{\alpha\beta} \chi^\beta = -\chi^\beta \epsilon_{\alpha\beta} \xi^\alpha = \chi^\beta \epsilon_{\beta\alpha} \xi^\alpha = \chi^\beta \epsilon_{\beta\dot{\alpha}} \xi_{\dot{\alpha}} \equiv \chi \xi \quad (2.15)$$

with, conveniently, no minus sign in the end. [A minus sign appeared in eq. (2.15) from exchanging the order of anticommuting spinors, but it disappeared due to the antisymmetry of the $\epsilon$ symbol.] Likewise, $\chi^\dagger \chi^\dagger$ and $\chi^\dagger \chi^\dagger$ are equivalent abbreviations for $\chi^\dagger_{\dot{\alpha}} \chi^\dagger_{\dot{\alpha}} = \chi^\dagger_{\dot{\alpha}} \chi^\dagger_{\dot{\alpha}}$, and in fact this is the complex conjugate of $\chi \chi$:

$$\xi^\dagger \chi^\dagger = \chi^\dagger \xi^\dagger = (\chi \chi)^*. \quad (2.16)$$
In a similar way, one can check that
\[ \xi^\dagger \sigma^\mu \chi = -\chi \sigma^\mu \xi^\dagger = (\chi^\dagger \sigma^\mu \xi)^* = - (\xi \sigma^\mu \chi^\dagger)^* \] (2.17)
stands for \( \xi_\alpha^\dagger (\sigma^\mu)^{\dot{\alpha} \alpha} \chi_\alpha \), etc. The anti-commuting spinors here are taken to be classical fields; for quantum fields the complex conjugation in the last two equations would be replaced by Hermitian conjugation in the Hilbert space operator sense.

Some other identities that will be useful below include:
\[ \xi \sigma^\mu \sigma^\nu \chi = \chi \sigma^\nu \sigma^\mu \xi = (\chi^\dagger \sigma^\nu \sigma^\mu \chi^\dagger)^* = (\xi^\dagger \sigma^\nu \sigma^\mu \chi^\dagger)^* \] (2.18)
and the Fierz rearrangement identity:
\[ \chi_\alpha \ (\xi \eta) = -\xi_\alpha \ (\eta \chi) - \eta_\alpha \ (\chi \xi), \] (2.19)
and the reduction identities
\[ \sigma^\mu \alpha \sigma_\mu^\beta = -2\delta^\beta_\alpha \delta^\beta_\alpha, \] (2.20)
\[ [\sigma^\mu \sigma^\nu + \sigma^\nu \sigma^\mu]_\alpha^\beta = -2\eta^\mu \nu \delta^\beta_\alpha, \] (2.21)
\[ [\sigma^\mu \sigma^\nu + \sigma^\nu \sigma^\mu]_\dot{\alpha}^\beta = -2\eta^\mu \nu \delta^\beta_\dot{\alpha}, \] (2.22)
\[ \sigma^\mu \sigma^\nu \sigma^\rho = -\eta^\mu \nu \sigma^\rho - \eta^\mu \rho \sigma^\nu - \eta^\nu \rho \sigma^\mu + i\epsilon^{\mu \nu \rho \kappa} \sigma_\kappa, \] (2.23)
\[ \sigma^\mu \sigma^\nu \sigma^\rho = -\eta^\mu \nu \sigma^\rho - \eta^\mu \rho \sigma^\nu - \eta^\nu \rho \sigma^\mu - i\epsilon^{\mu \nu \rho \kappa} \sigma_\kappa, \] (2.24)
where \( \epsilon^{\mu \nu \rho \kappa} \) is the totally antisymmetric tensor with \( \epsilon^{0123} = +1 \).

With these conventions, the Dirac Lagrangian eq. (2.5) can now be rewritten:
\[ \mathcal{L}_{\text{Dirac}} = -i\xi^\dagger \sigma^\mu \partial_\mu \xi - i\chi^\dagger \sigma^\mu \partial_\mu \chi - M(\xi \chi + \xi^\dagger \chi^\dagger) \] (2.25)
where we have dropped a total derivative piece \( i\partial_\mu (\chi^\dagger \sigma^\mu \chi) \), which does not affect the action.

A four-component Majorana spinor can be obtained from the Dirac spinor of eq. (2.9) by imposing the constraint \( \chi = \xi \), so that
\[ \Psi_M = \begin{pmatrix} \xi_\alpha \\ \xi^\dagger_\dot{\alpha} \end{pmatrix}, \quad \Psi_M^* = \begin{pmatrix} \xi^\dagger_\alpha \\ \xi_\dot{\alpha} \end{pmatrix}. \] (2.26)
The four-component spinor form of the Lagrangian for a Majorana fermion with mass \( M \),
\[ \mathcal{L}_{\text{Majorana}} = -i \frac{\bar{\Psi}_M \gamma^\mu \partial_\mu \Psi_M}{2} - \frac{1}{2} M \bar{\Psi}_M \Psi_M \] (2.27)
can therefore be rewritten as
\[ \mathcal{L}_{\text{Majorana}} = -i \xi^\dagger \sigma^\mu \partial_\mu \xi - \frac{1}{2} M(\xi \xi + \xi^\dagger \xi^\dagger) \] (2.28)
in the more economical two-component Weyl spinor representation. Note that even though \( \xi_\alpha \) is anticommuting, \( \xi \xi \) and its complex conjugate \( \xi^\dagger \xi^\dagger \) do not vanish, because of the suppressed \( \epsilon \) symbol, see eq. (2.15). Explicitly, \( \xi \xi = \epsilon^{\alpha \beta} \xi^\beta \xi_\alpha = \xi_2 \xi_1 - \xi_1 \xi_2 = 2 \xi_2 \xi_1 \).

More generally, any theory involving spin-1/2 fermions can always be written down in terms of a collection of left-handed Weyl spinors \( \psi_i \) with
\[ \mathcal{L} = -i \bar{\psi}_i \gamma^\mu \partial_\mu \psi_i + \ldots \] (2.29)
where the ellipses represent possible mass terms, gauge interactions, and Yukawa interactions with scalar fields. Here the index \( i \) runs over the appropriate gauge and flavor indices of the fermions;
it is raised or lowered by Hermitian conjugation. Gauge interactions are obtained by promoting the ordinary derivative to a gauge-covariant derivative:

$$\mathcal{L} = -i\psi^i \sigma^\mu D_\mu \psi_i + \ldots \quad (2.30)$$

with

$$D_\mu \psi_i = \partial_\mu \psi_i - ig_a A^a_\mu T^a_i \psi_i,$$ \quad (2.31)

where $g_a$ is the gauge coupling corresponding to the Hermitian Lie algebra generator $T^a$ with vector field $A^a_\mu$.

There is a different $\psi_i$ for the left-handed piece and for the hermitian conjugate of the right-handed piece of a Dirac fermion. Given any expression involving bilinears of four-component spinors

$$\Psi_i = (\xi_i \chi_i^\dagger), \quad (2.32)$$

labeled by a flavor or gauge-representation index $i$, one can translate into two-component Weyl spinor language (or vice versa) using the dictionary:

$$\bar{\Psi}_i P_L \Psi_j = \chi_i \xi_j, \quad \bar{\Psi}_i P_R \Psi_j = \xi_i^\dagger \chi_j^\dagger,$$ \quad (2.33)

$$\bar{\Psi}_i \gamma^\mu P_L \Psi_j = \xi_i^\dagger \sigma^\mu \xi_j, \quad \bar{\Psi}_i \gamma^\mu P_R \Psi_j = \chi_i \sigma^\mu \chi_j^\dagger,$$ \quad (2.34)

etc.

Let us now see how the Standard Model quarks and leptons are described in this notation. The complete list of left-handed Weyl spinors can be given names corresponding to the chiral supermultiplets in Table 1.1:

$$Q_i = \begin{pmatrix} u \\ d \end{pmatrix}, \quad (2.35)$$

$$\bar{Q}_i = \bar{u}, \bar{d}, \bar{t}, \bar{c}, \bar{s}, \bar{b}, \quad (2.36)$$

$$L_i = \begin{pmatrix} \nu_e \\ e \end{pmatrix}, \quad (2.37)$$

$$\bar{L}_i = \bar{\nu}_e, \bar{\nu}_\mu, \bar{\nu}_\tau, \bar{e}, \bar{\mu}, \bar{\tau}, \quad (2.38)$$

Here $i = 1, 2, 3$ is a family index. The bars on these fields are part of the names of the fields, and do not denote any kind of conjugation. Rather, the unbarred fields are the left-handed pieces of a Dirac spinor, while the barred fields are the names given to the conjugates of the right-handed piece of a Dirac spinor. For example, $e$ is the same thing as $e_L$ in Table 1.1 and $\bar{e}$ is the same as $e_R^\dagger$. Together they form a Dirac spinor:

$$\begin{pmatrix} e \\ \bar{e}^\dagger \end{pmatrix} \equiv \begin{pmatrix} e_L \\ e_R \end{pmatrix}, \quad (2.40)$$

and similarly for all of the other quark and charged lepton Dirac spinors. (The neutrinos of the Standard Model are not part of a Dirac spinor, at least in the approximation that they are massless.) The fields $Q_i$ and $L_i$ are weak isodoublets, which always go together when one is constructing interactions invariant under the full Standard Model gauge group $SU(3)_C \times SU(2)_L \times U(1)_Y$. Suppressing all color and weak isospin indices, the kinetic and gauge part of the Standard Model fermion Lagrangian density is then

$$\mathcal{L} = -i Q^i \sigma^\mu D_\mu Q_i - i \bar{Q}_i^\dagger \sigma^\mu D_\mu Q_i - i \bar{L}_i^\dagger \sigma^\mu D_\mu L_i - i e^i \sigma^\mu D_\mu e_i - i \bar{e_i}^\dagger \sigma^\mu D_\mu \bar{e}_i \quad (2.41)$$
with the family index $i$ summed over, and $D_\mu$ the appropriate Standard Model covariant derivative. For example,

$$
D_\mu \left( \nu_e \right) = \left[ \partial_\mu - igW_\mu^a (\tau^a/2) - ig' Y_L B_\mu \right] \nu_e
$$

(2.42)

$$
D_\mu \bar{\nu} = \left[ \partial_\mu - ig' Y_L B_\mu \right] \bar{\nu}
$$

(2.43)

with $\tau^a (a = 1, 2, 3)$ equal to the Pauli matrices, $Y_L = -1/2$ and $Y_{\bar{\nu}} = +1$. The gauge eigenstate weak bosons are related to the mass eigenstates by

$$
W_\mu^\pm = \left( W_\mu^1 \mp iW_\mu^2 / \sqrt{2} \right),
$$

(2.44)

$$
\begin{pmatrix}
Z_\mu \\ A_\mu
\end{pmatrix} = \begin{pmatrix}
\cos \theta_W & -\sin \theta_W \\
\sin \theta_W & \cos \theta_W
\end{pmatrix}
\begin{pmatrix}
W_\mu^3 \\ B_\mu
\end{pmatrix}.
$$

(2.45)

Similar expressions hold for the other quark and lepton gauge eigenstates, with $Y_Q = 1/6$, $Y_{\bar{\nu}} = -2/3$, and $Y_{\bar{d}} = 1/3$. The quarks also have a term in the covariant derivative corresponding to gluon interactions proportional to $g_3$ (with $\alpha_S = g_3^2/4\pi$) with generators $T^a = \lambda^a/2$ for $Q$, and in the complex conjugate representation $T^a = -(\lambda^a)^*/2$ for $\overline{\tau}$ and $\overline{d}$, where $\lambda^a$ are the Gell-Mann matrices.

### 3 Supersymmetric Lagrangians

In this section we will describe the construction of supersymmetric Lagrangians. Our aim is to arrive at a recipe that will allow us to write down the allowed interactions and mass terms of a general supersymmetric theory, so that later we can apply the results to the special case of the MSSM. We will not use the superfield language, which is often more elegant and efficient for those who know it, but might seem rather cabalistic to some. Our approach is therefore intended to be complementary to the superspace and superfield derivations given in other works. We begin by considering the simplest example of a supersymmetric theory in four dimensions.

#### 3.1 The simplest supersymmetric model: a free chiral supermultiplet

The minimum fermion content of a field theory in four dimensions consists of a single left-handed two-component Weyl fermion $\psi$. Since this is an intrinsically complex object, it seems sensible to choose as its superpartner a complex scalar field $\phi$. The simplest action we can write down for these fields just consists of kinetic energy terms for each:

$$
S = \int d^4x \left( \mathcal{L}_{\text{scalar}} + \mathcal{L}_{\text{fermion}} \right),
$$

(3.1)

$$
\mathcal{L}_{\text{scalar}} = -\partial^\mu \phi^* \partial_\mu \phi, \quad \mathcal{L}_{\text{fermion}} = -i \bar{\psi} \gamma^\mu \partial_\mu \psi.
$$

(3.2)

This is called the massless, non-interacting Wess-Zumino model [10], and it corresponds to a single chiral supermultiplet as discussed in the Introduction.

A supersymmetry transformation should turn the scalar boson field $\phi$ into something involving the fermion field $\psi$. The simplest possibility for the transformation of the scalar field is

$$
\delta \phi = \epsilon \psi, \quad \delta \phi^* = \epsilon^\dagger \psi^\dagger,
$$

(3.3)

where $\epsilon^a$ is an infinitesimal, anticommuting, two-component Weyl fermion object parameterizing the supersymmetry transformation. Until section 6.5 we will be discussing global supersymmetry, which means that $\epsilon^a$ is a constant, satisfying $\partial_\mu \epsilon^a = 0$. Since $\psi$ has dimensions of $[\text{mass}]^{3/2}$ and $\phi$ has
dimensions of [mass], it must be that $\epsilon$ has dimensions of [mass]$^{-1/2}$. Using eq. (3.3), we find that the scalar part of the Lagrangian transforms as

$$\delta \mathcal{L}_{\text{scalar}} = -\epsilon \partial^\mu \psi \partial_\mu \phi^* - \epsilon \partial^\mu \psi^\dagger \partial_\mu \phi.$$  

(3.4)

We would like for this to be canceled by $\delta \mathcal{L}_{\text{fermion}}$, at least up to a total derivative, so that the action will be invariant under the supersymmetry transformation. Comparing eq. (3.3) with $\mathcal{L}_{\text{fermion}}$, we see that for this to have any chance of happening, $\delta \psi$ should be linear in $\epsilon^\dagger$ and in $\phi$, and should contain one spacetime derivative. Up to a multiplicative constant, there is only one possibility to try:

$$\delta \psi_\alpha = i(\sigma^\mu \epsilon^\dagger)_\alpha \partial_\mu \phi, \quad \delta \psi^\dagger_\alpha = -i(\epsilon^\mu)_\alpha \partial_\mu \phi^*.$$  

(3.5)

With this guess, one immediately obtains

$$\delta \mathcal{L}_{\text{fermion}} = -\epsilon \sigma^\nu \partial_\nu \psi \partial_\mu \phi^* + \psi^\dagger \sigma^\nu \epsilon^\dagger \partial_\nu \phi.$$  

(3.6)

This can be put in a slightly more useful form by employing the Pauli matrix identities eqs. (2.21), (2.22) and using the fact that partial derivatives commute ($\partial_\mu \partial_\nu = \partial_\nu \partial_\mu$). Equation (3.6) then becomes

$$\delta \mathcal{L}_{\text{fermion}} = \epsilon \partial^\mu \psi \partial_\mu \phi^* + \epsilon^\dagger \partial^\mu \psi^\dagger \partial_\mu \phi$$

$$- \partial_\mu \left( \epsilon \sigma^\nu \partial_\nu \psi \partial_\mu \phi^* + \epsilon \psi \partial_\mu \phi^* + \epsilon^\dagger \psi^\dagger \partial_\mu \phi \right).$$  

(3.7)

The first two terms here just cancel against $\delta \mathcal{L}_{\text{scalar}}$, while the remaining contribution is a total derivative. So we arrive at

$$\delta S = \int d^2 x \ (\delta \mathcal{L}_{\text{scalar}} + \delta \mathcal{L}_{\text{fermion}}) = 0,$$  

(3.8)

justifying our guess of the numerical multiplicative factor made in eq. (3.5).

We are not quite finished in showing that the theory described by eq. (3.1) is supersymmetric. We must also show that the supersymmetry algebra closes; in other words, that the commutator of two supersymmetry transformations parameterized by two different spinors $\epsilon_1$ and $\epsilon_2$ is another symmetry of the theory. Using eq. (3.5) in eq. (3.6), one finds

$$(\delta_2 \delta_1 - \delta_1 \delta_2) \phi = \epsilon_2 (\delta_1 \phi) - \delta_1 (\delta_2 \phi) = i(\epsilon_1 \sigma^\mu \epsilon_2^\dagger - \epsilon_2 \sigma^\mu \epsilon_1^\dagger) \partial_\mu \phi.$$  

(3.9)

This is a remarkable result; in words, we have found that the commutator of two supersymmetry transformations gives us back the derivative of the original field. Since $\partial_\mu$ corresponds to the generator of spacetime translations $P_\mu$, eq. (3.9) implies the form of the supersymmetry algebra that was foreshadowed in eq. (1.6) of the Introduction. (We will make this statement more explicit before the end of this section.)

All of this will be for nothing if we do not find the same result for the fermion $\psi$. Using eq. (3.5) in eqs. (3.6), we get

$$(\delta_2 \delta_1 - \delta_1 \delta_2) \psi_\alpha = i(\sigma^\mu \epsilon_1^\dagger)_\alpha \epsilon_2 \partial_\mu \psi - i(\sigma^\mu \epsilon_2)_\alpha \epsilon_1 \partial_\mu \psi.$$  

(3.10)

This can be put into a more useful form by applying the Fierz identity eq. (2.19) with $\chi = \sigma^\mu \epsilon_1^\dagger$, $\xi = \epsilon_2$, $\eta = \partial_\mu \psi$, and again with $\chi = \sigma^\mu \epsilon_2^\dagger$, $\xi = \epsilon_1$, $\eta = \partial_\mu \psi$, followed in each case by an application of the identity eq. (2.17). The result is

$$(\delta_2 \delta_1 - \delta_1 \delta_2) \psi_\alpha = i(\epsilon_1 \sigma^\mu \epsilon_2^\dagger - \epsilon_2 \sigma^\mu \epsilon_1^\dagger) \partial_\mu \psi_\alpha - i \epsilon_1 \omega_1 \epsilon_2 \sigma^\mu \partial_\mu \psi + i \epsilon_2 \epsilon_1 \omega_1 \sigma^\mu \partial_\mu \psi.$$  

(3.11)
The last two terms in (3.11) vanish on-shell; that is, if the equation of motion \( \bar{\sigma}^\mu \partial_\mu \psi = 0 \) following from the action is enforced. The remaining piece is exactly the same spacetime translation that we found for the scalar field.

The fact that the supersymmetry algebra only closes on-shell (when the classical equations of motion are satisfied) might be somewhat worrisome, since we would like the symmetry to hold even quantum mechanically. This can be fixed by a trick. We invent a new complex scalar field \( F \), which does not have a kinetic term. Such fields are called auxiliary, and they are really just book-keeping devices that allow the symmetry algebra to close off-shell. The Lagrangian density for \( F \) and its complex conjugate is simply

\[
L_{\text{auxiliary}} = F^* F. \tag{3.12}
\]

The dimensions of \( F \) are \([\text{mass}]^2\), unlike an ordinary scalar field, which has dimensions of \([\text{mass}]\). Equation (3.12) implies the not-very-exciting equations of motion \( F = F^* = 0 \). However, we can use the auxiliary fields to our advantage by including them in the supersymmetry transformation rules. In view of eq. (3.11), a plausible thing to do is to make \( F \) transform into a multiple of the equation of motion for \( \psi \):

\[
\delta F = i \epsilon \sigma^\mu \partial_\mu \psi, \quad \delta F^* = -i \partial_\mu \psi^\dagger \sigma^\mu \epsilon. \tag{3.13}
\]

Once again we have chosen the overall factor on the right-hand sides by virtue of foresight. Now the auxiliary part of the Lagrangian density transforms as

\[
\delta L_{\text{auxiliary}} = i \epsilon \sigma^\mu \partial_\mu \psi F^* - i \partial_\mu \psi^\dagger \sigma^\mu \epsilon F, \tag{3.14}
\]

which vanishes on-shell, but not for arbitrary off-shell field configurations. Now, by adding an extra term to the transformation law for \( \psi \) and \( \psi^\dagger \):

\[
\delta \psi_\alpha = i (\sigma^\mu \epsilon^\dagger)_\alpha \partial_\mu \phi + \epsilon_\alpha F, \quad \delta \psi^\dagger_\dot{\alpha} = -i (\epsilon \sigma^\mu)_{\dot{\alpha}} \partial_\mu \phi^* + \bar{\epsilon}^\dagger_{\dot{\alpha}} F^*, \tag{3.15}
\]

one obtains an additional contribution to \( \delta L_{\text{fermion}} \), which just cancels with \( \delta L_{\text{auxiliary}} \), up to a total derivative term. So our “modified” theory with \( \mathcal{L} = L_{\text{scalar}} + L_{\text{fermion}} + L_{\text{auxiliary}} \) is still invariant under supersymmetry transformations. Proceeding as before, one now obtains for each of the fields \( X = \phi, \phi^*, \psi, \psi^\dagger, F, F^* \),

\[
(\delta_\epsilon_2 \delta_\epsilon_1 - \delta_\epsilon_1 \delta_\epsilon_2) X = i (\epsilon_1 \sigma^\mu \epsilon^\dagger_2 - \epsilon_2 \sigma^\mu \epsilon^\dagger_1) \partial_\mu X \tag{3.16}
\]

using eqs. (5.3), (5.13), and (5.15), but now without resorting to any of the equations of motion. So we have succeeded in showing that supersymmetry is a valid symmetry of the Lagrangian off-shell.

In retrospect, one can see why we needed to introduce the auxiliary field \( F \) in order to get the supersymmetry algebra to work off-shell. On-shell, the complex scalar field \( \phi \) has two real propagating degrees of freedom, matching the two spin polarization states of \( \psi \). Off-shell, however, the Weyl fermion \( \psi \) is a complex two-component object, so it has four real degrees of freedom. (Going on-shell eliminates half of the propagating degrees of freedom for \( \psi \), because the Lagrangian is linear in time derivatives, so that the canonical momenta can be reexpressed in terms of the configuration variables without time derivatives and are not independent phase space coordinates.) To make the numbers of bosonic and fermionic degrees of freedom match off-shell as well as on-shell, we had to introduce two more real scalar degrees of freedom in the complex field \( F \), which are eliminated when one goes on-shell. This counting is summarized in Table 3.1. The auxiliary field formulation is especially useful when discussing spontaneous supersymmetry breaking, as we will see in section 6.

Invariance of the action under a symmetry transformation always implies the existence of a conserved current, and supersymmetry is no exception. The supercurrent \( J_5^\mu \) is an anticommuting four-vector. It also carries a spinor index, as befits the current associated with a symmetry with fermionic
generators [51]. By the usual Noether procedure, one finds for the supercurrent (and its hermitian conjugate) in terms of the variations of the fields \( X = \phi, \phi^*, \psi, \psi^*, F, F^* \):

\[
\epsilon J^\mu + \epsilon^\dagger J^{\dagger \mu} \equiv \sum_X \delta X \frac{\delta \mathcal{L}}{\delta (\partial^\mu X)} - K^\mu,
\]

where \( K^\mu \) is an object whose divergence is the variation of the Lagrangian density under the supersymmetry transformation, \( \delta \mathcal{L} = \partial_\mu K^\mu \). Note that \( K^\mu \) is not unique; one can always replace \( K^\mu \) by \( K^\mu + k^\mu \), where \( k^\mu \) is any vector satisfying \( \partial^\mu k^\mu = 0 \), for example \( k^\mu = \partial^\mu \partial^\nu a^\nu - \partial_\nu \partial^\nu a^\mu \). A little work reveals that, up to the ambiguity just mentioned,

\[
J^\mu_\alpha = (\sigma^\nu \sigma^\mu \psi)_\alpha \partial_\nu \phi^*, \quad J^{\dagger \mu}_\alpha = (\psi^\dagger \sigma^\mu \sigma^\nu)_\alpha \partial_\nu \phi.
\]

The supercurrent and its hermitian conjugate are separately conserved:

\[
\partial_\mu J^\mu_\alpha = 0, \quad \partial_\mu J^{\dagger \mu}_\alpha = 0,
\]

as can be verified by use of the equations of motion. From these currents one constructs the conserved charges

\[
Q_\alpha = \sqrt{2} \int d^3 \bar{x} J^0_\alpha, \quad Q^\dagger_\alpha = \sqrt{2} \int d^3 \bar{x} J^0_{\alpha \dagger},
\]

which are the generators of supersymmetry transformations. (The factor of \( \sqrt{2} \) normalization is included to agree with an arbitrary historical convention.) As quantum mechanical operators, they satisfy

\[
\left[ \epsilon Q + \epsilon^\dagger Q^\dagger, X \right] = -i \sqrt{2} \delta X
\]

for any field \( X \), up to terms that vanish on-shell. This can be verified explicitly by using the canonical equal-time commutation and anticommutation relations

\[
\begin{align*}
[\phi(\bar{x}), \pi(\bar{y})] &= [\phi^*(\bar{x}), \pi^*(\bar{y})] = i \delta^{(3)}(\bar{x} - \bar{y}), \\
\{\psi_\alpha(\bar{x}), \psi^\dagger_\beta(\bar{y})\} &= (\sigma_0)_{\alpha \beta} \delta^{(3)}(\bar{x} - \bar{y})
\end{align*}
\]

derived from the free field theory Lagrangian eq. (3.1). Here \( \pi = \partial_0 \phi^* \) and \( \pi^* = \partial_0 \phi \) are the momenta conjugate to \( \phi \) and \( \phi^* \) respectively.

Using eq. (3.21), the content of eq. (3.16) can be expressed in terms of canonical commutators as

\[
\left[ \epsilon_2 Q + \epsilon^\dagger_2 Q^\dagger, [\epsilon_1 Q + \epsilon^\dagger_1 Q^\dagger, X] \right] - \left[ \epsilon_1 Q + \epsilon^\dagger_1 Q^\dagger, [\epsilon_2 Q + \epsilon^\dagger_2 Q^\dagger, X] \right] = 2(\epsilon_2 \sigma^\mu \epsilon^\dagger_1 - \epsilon_1 \sigma^\mu \epsilon^\dagger_2) i \partial_\mu X,
\]

up to terms that vanish on-shell. The spacetime momentum operator is \( P^\mu = (H, \vec{P}) \), where \( H \) is the Hamiltonian and \( \vec{P} \) is the three-momentum operator, given in terms of the canonical variables by

\[
H = \int d^3 \bar{x} \left[ \pi^\dagger \pi + (\vec{\nabla} \phi^*) \cdot (\vec{\nabla} \phi) + i \psi^\dagger \vec{\sigma} \cdot \vec{\nabla} \psi \right],
\]

\[
\vec{P} = -\int d^3 \bar{x} \left( \vec{\nabla} \phi + \pi^\dagger \vec{\nabla} \phi^* + i \psi^\dagger \vec{\sigma}, \vec{\nabla} \psi \right).
\]

Table 3.1: Counting of real degrees of freedom in the Wess-Zumino model.

It generates spacetime translations on the fields $X$ according to

$$[P^\mu, X] = i\partial^\mu X.$$  \hspace{1cm} (3.27)

Rearranging the terms in eq. (3.24) using the Jacobi identity, we therefore have

$$[\epsilon_2 Q + \epsilon_2^\dagger Q^\dagger, \epsilon_1 Q + \epsilon_1^\dagger Q^\dagger, X] = 2(\epsilon_2 \sigma_\mu \epsilon_1^\dagger - \epsilon_1 \sigma_\mu \epsilon_2^\dagger) [P^\mu, X],$$  \hspace{1cm} (3.28)

for any $X$, up to terms that vanish on-shell, so it must be that

$$[\epsilon_2 Q + \epsilon_2^\dagger Q^\dagger, \epsilon_1 Q + \epsilon_1^\dagger Q^\dagger] = 2(\epsilon_2 \sigma_\mu \epsilon_1^\dagger - \epsilon_1 \sigma_\mu \epsilon_2^\dagger) P^\mu.$$  \hspace{1cm} (3.29)

Now by expanding out eq. (3.29), one obtains the precise form of the supersymmetry algebra relations

$$\{Q_\alpha, Q_\bar{\alpha}\} = 2\sigma_\mu^{\alpha\bar{\alpha}} P_\mu,$$  \hspace{1cm} (3.30)

$$\{Q_\alpha, Q_\beta\} = 0, \quad \{Q_\bar{\alpha}, Q_\bar{\beta}\} = 0,$$  \hspace{1cm} (3.31)

as promised in the Introduction. [The commutator in eq. (3.29) turns into anticommutators in eqs. (3.30) and (3.31) in the process of extracting the anticommuting spinors $\epsilon_1$ and $\epsilon_2$.] The results follow immediately from eq. (3.27) and the fact that the supersymmetry transformations are global (independent of position in spacetime). This demonstration of the supersymmetry algebra in terms of the canonical generators $Q$ and $Q^\dagger$ requires the use of the Hamiltonian equations of motion, but the symmetry itself is valid off-shell at the level of the Lagrangian, as we have already shown.

### 3.2 Interactions of chiral supermultiplets

In a realistic theory like the MSSM, there are many chiral supermultiplets, with both gauge and non-gauge interactions. In this subsection, our task is to construct the most general possible theory of gauge and non-gauge couplings, including mass terms, for particles that live in chiral supermultiplets. In the MSSM these are the quarks, squarks, leptons, sleptons, Higgs scalars and higgsino fermions. We will find that the gauge interactions. In this subsection, our task is to construct the most general possible theory of interactions of chiral supermultiplets.

Our starting point is the Lagrangian density for a collection of free chiral supermultiplets labeled by an index $i$, which runs over all gauge and flavor degrees of freedom. Since we will want to construct an interacting theory with supersymmetry closing off-shell, each supermultiplet contains a complex scalar $\phi_i$ and a left-handed Weyl fermion $\psi_i$ as physical degrees of freedom, plus a complex auxiliary field $F_i$, which does not propagate. The results of the previous subsection tell us that the free part of the Lagrangian is

$$\mathcal{L}_{\text{free}} = -\partial^\mu \phi_i^* \partial_\mu \phi_i - i\psi_i^\dagger \sigma^\mu \partial_\mu \psi_i + F_i^* F_i,$$  \hspace{1cm} (3.33)

where we sum over repeated indices $i$ (not to be confused with the suppressed spinor indices), with the convention that fields $\phi$ and $\psi$ always carry lowered indices, while their conjugates always carry raised indices. It is invariant under the supersymmetry transformation

$$\delta \phi_i = e \psi_i,$$

$$\delta (\psi_i)_a = i(\sigma^\mu \epsilon^\dagger)_a \partial_\mu \phi_i + \epsilon_a F_i,$$

$$\delta F_i = i\epsilon^\dagger \sigma^\mu \partial_\mu \psi_i,$$

$$\delta \phi_i^* = \epsilon^\dagger \psi_i^\dagger,$$

$$\delta (\psi_i^\dagger)_a = -i(\epsilon \sigma^\mu)_a \partial_\mu \phi_i^* + \epsilon_a^\dagger F_i^*,$$

$$\delta F_i^* = -i\partial_\mu \psi_i^\dagger \sigma^\mu \epsilon .$$  \hspace{1cm} (3.34)
We will now find the most general set of renormalizable interactions for these fields that is consistent with supersymmetry. We do this working in the field theory before integrating out the auxiliary fields. To begin, note that in order to be renormalizable by power counting, each term must have field content with total mass dimension \( \leq 4 \). So, the only candidate terms are:

\[
\mathcal{L}_{\text{int}} = \left( -\frac{1}{2} W^{ij} \psi_i \psi_j + W^i F_i + x^{ij} F_i F_j \right) + \text{c.c.} - U, \tag{3.37}
\]

where \( W^{ij}, W^i, x^{ij}, \) and \( U \) are polynomials in the scalar fields \( \phi_i, \phi^* \), with degrees 1, 2, 0, and 4, respectively. [Terms of the form \( F^{*i} F_j \) are already included in eq. (3.33), with the coefficient fixed by the transformation rules (3.34)-(3.36).]

We must now require that \( \mathcal{L}_{\text{int}} \) is invariant under the supersymmetry transformations, since \( \mathcal{L}_{\text{free}} \) was already invariant by itself. This immediately requires that the candidate term \( U(\phi_i, \phi^* \) must vanish. If there were such a term, then under a supersymmetry transformation eq. (3.34) it would transform into another function of the scalar fields only, multiplied by \( \epsilon \psi_i \) or \( \epsilon^i \psi^i \), and with no spacetime derivatives or \( F_i, F^* \) fields. It is easy to see from eqs. (3.34)-(3.37) that nothing of this form can possibly be canceled by the supersymmetry transformation of any other term in the Lagrangian. Similarly, the dimensionless coupling \( x^{ij} \) must be zero, because its supersymmetry transformation likewise cannot possibly be canceled by any other term. So, we are left with

\[
\mathcal{L}_{\text{int}} = \left( -\frac{1}{2} W^{ij} \psi_i \psi_j + W^i F_i \right) + \text{c.c.} \tag{3.38}
\]

as the only possibilities. At this point, we are not assuming that \( W^{ij} \) and \( W^i \) are related to each other in any way. However, soon we will find out that they are related, which is why we have chosen to use the same letter for them. Notice that eq. (3.41) tells us that \( W^{ij} \) is symmetric under \( i \leftrightarrow j \).

It is easiest to divide the variation of \( \mathcal{L}_{\text{int}} \) into several parts, which must cancel separately. First, we consider the part that contains four spinors:

\[
\delta \mathcal{L}_{\text{int}}|_{4-\text{spinor}} = \left[ -\frac{1}{2} \delta W^{ij} (\epsilon \psi_k)(\psi_i \psi_j) - \frac{1}{2} \delta W^{ij} (\epsilon^i \psi^j k)(\psi_i \psi_j) \right] + \text{c.c.} \tag{3.39}
\]

The term proportional to \((\epsilon \psi_k)(\psi_i \psi_j)\) cannot cancel against any other term. Fortunately, however, the Fierz identity eq. (2.19) implies

\[
(\epsilon \psi_i)(\psi_j \psi_k) + (\epsilon \psi_j)(\psi_k \psi_i) + (\epsilon \psi_k)(\psi_i \psi_j) = 0, \tag{3.40}
\]

so this contribution to \( \delta \mathcal{L}_{\text{int}} \) vanishes identically if and only if \( \delta W^{ij}/\delta \phi_k \) is totally symmetric under interchange of \( i, j, k \). There is no such identity available for the term proportional to \((\epsilon^i \psi^j k)(\psi_i \psi_j)\). Since that term cannot cancel with any other, requiring it to be absent just tells us that \( W^{ij} \) cannot contain \( \phi^* k \). In other words, \( W^{ij} \) is analytic (or holomorphic) in the complex fields \( \phi_k \).

Combining what we have learned so far, we can write

\[
W^{ij} = M^{ij} + y^{ijk} \phi_k \tag{3.41}
\]

where \( M^{ij} \) is a symmetric mass matrix for the fermion fields, and \( y^{ijk} \) is a Yukawa coupling of a scalar \( \phi_k \) and two fermions \( \psi_i \psi_j \) that must be totally symmetric under interchange of \( i, j, k \). It is therefore possible, and it turns out to be convenient, to write

\[
W^{ij} = \frac{\delta^2}{\delta \phi_i \delta \phi_j} W \tag{3.42}
\]
where we have introduced a useful object

\[ W = \frac{1}{2} M^{ij} \phi_i \phi_j + \frac{1}{6} g^{ijk} \phi_i \phi_j \phi_k, \]

(3.43)
called the superpotential. This is not a scalar potential in the ordinary sense; in fact, it is not even real. It is instead an analytic function of the scalar fields \( \phi_i \) treated as complex variables.

Continuing on our vaunted quest, we next consider the parts of \( \delta L_{\text{int}} \) that contain a spacetime derivative:

\[ \delta L_{\text{int}} |_\partial = \left( -i W^{ij} \partial_\mu \phi_j \psi_i \sigma^\mu \epsilon^\dagger - i W^i \partial_\mu \psi_i \sigma^\mu \epsilon^\dagger \right) + \text{c.c.} \]  
(3.44)

Here we have used the identity eq. (2.17) on the second term, which came from \( (\delta F_i) W^i \). Now we can use eq. (3.42) to observe that

\[ W^{ij} \partial_\mu \phi_j = \partial_\mu \left( \frac{\delta W}{\delta \phi_i} \right). \]  
(3.45)

Therefore, eq. (3.44) will be a total derivative if

\[ W^i = \frac{\delta W}{\delta \phi_i} = M^{ij} \phi_j + \frac{1}{2} g^{ijk} \phi_i \phi_j \phi_k, \]

(3.46)

which explains why we chose its name as we did. The remaining terms in \( \delta L_{\text{int}} \) are all linear in \( F_i \) or \( F^*_i \), and it is easy to show that they cancel, given the results for \( W^i \) and \( W^{ij} \) that we have already found.

Actually, we can include a linear term in the superpotential without disturbing the validity of the previous discussion at all:

\[ W = L^i \phi_i + \frac{1}{2} M^{ij} \phi_i \phi_j + \frac{1}{6} g^{ijk} \phi_i \phi_j \phi_k. \]

(3.47)

Here \( L^i \) are parameters with dimensions of \([\text{mass}]^2\), which affect only the scalar potential part of the Lagrangian. Such linear terms are only allowed when \( \phi_i \) is a gauge singlet, and there are no such gauge singlet chiral supermultiplets in the MSSM with minimal field content. I will therefore omit this term from the remaining discussion of this section. However, this type of term does play an important role in the discussion of spontaneous supersymmetry breaking, as we will see in section 6.1.

To recap, we have found that the most general non-gauge interactions for chiral supermultiplets are determined by a single analytic function of the complex scalar fields, the superpotential \( W \). The auxiliary fields \( F_i \) and \( F^*_i \) can be eliminated using their classical equations of motion. The part of \( \mathcal{L}_{\text{free}} + \mathcal{L}_{\text{int}} \) that contains the auxiliary fields is \( F_i F^*_i + W^i F_i + W^*_i F^*_i \), leading to the equations of motion

\[ F_i = -W^*_i, \quad F^*_i = -W^i. \]  
(3.48)

Thus the auxiliary fields are expressible algebraically (without any derivatives) in terms of the scalar fields.

After making the replacement\(^\dagger\) eq. (3.48) in \( \mathcal{L}_{\text{free}} + \mathcal{L}_{\text{int}} \), we obtain the Lagrangian density

\[ \mathcal{L} = -\partial^\mu \phi^*_i \partial_\mu \phi_i - i \psi^*_i \sigma^\mu \partial_\mu \psi_i - \frac{1}{2} \left( W^{ij} \psi_i \psi_j + W^{*ij} \psi^*_i \psi^*_j \right) - W^i W^*_i. \]  
(3.49)

\(^\dagger\)Since \( F_i \) and \( F^*_i \) appear only quadratically in the action, the result of instead doing a functional integral over them at the quantum level has precisely the same effect.
Now that the non-propagating fields $F_i, F^*i$ have been eliminated, it follows from eq. (3.49) that the scalar potential for the theory is just given in terms of the superpotential by

$$V(\phi, \phi^*) = W^k W_k^* = F^{*k} F_k = M_{ik}^* M^{kj} \phi^i \phi_j + \frac{1}{2} M^{im} y_{jkn} \phi_i \phi^j \phi^k + \frac{1}{2} M^{*i} y_{kn} \phi^i \phi_j + M_{ik} \phi^i \phi_j + \frac{1}{4} y_{jkn} \phi^i \phi_j \phi^k \phi^l. \quad (3.50)$$

This scalar potential is automatically bounded from below; in fact, since it is a sum of squares of absolute values (of the $W^k$), it is always non-negative. If we substitute the general form for the superpotential eq. (3.43) into eq. (3.49), we obtain for the full Lagrangian density

$$\mathcal{L} = -\partial^\mu \phi^i \partial_\mu \phi_i - V(\phi, \phi^*) - i \bar{\psi} \gamma^\mu \sigma^\mu \partial_\mu \psi_i - \frac{1}{2} M^{ij} \bar{\psi}_i \psi_j - \frac{1}{2} M^{ij} \bar{\psi}_i \psi_j + \frac{1}{2} M^{*ij} \bar{\psi}_i \psi^j + \frac{1}{2} M^{*ij} \bar{\psi}_i \psi^j. \quad (3.51)$$

Now we can compare the masses of the fermions and scalars by looking at the linearized equations of motion:

$$\partial^\mu \partial_\mu \phi_i = M_{ik}^* M^{kj} \phi_j + \ldots, \quad \partial^\mu \partial_\mu \psi_i = M_{ij}^* M^{kl} \psi_j + \ldots, \quad \partial^\mu \partial_\mu \psi^i = M_{ij}^* M^{kl} \psi_j + \ldots. \quad (3.52)$$

One can eliminate $\psi$ in terms of $\psi^\dagger$ and vice versa in eq. (3.53), obtaining [after use of the identities eqs. (2.21) and (2.22)]:

$$\partial^\mu \partial_\mu \bar{\psi}_i = M_{ik}^* M^{kj} \bar{\psi}_j + \ldots, \quad \partial^\mu \partial_\mu \psi^i = \psi^i M_{ik}^* M^{kj} + \ldots. \quad (3.54)$$

Therefore, the fermions and the bosons satisfy the same wave equation with exactly the same squared-mass matrix with real non-negative eigenvalues, namely $(M^2)_i^j = M_{ik}^* M^{kj}$. It follows that diagonalizing this matrix by redefining the fields with a unitary matrix gives a collection of chiral supermultiplets, each of which contains a mass-degenerate complex scalar and Weyl fermion, in agreement with the general argument in the Introduction.

### 3.3 Lagrangians for gauge supermultiplets

The propagating degrees of freedom in a gauge supermultiplet are a massless gauge boson field $A^a_\mu$ and a two-component Weyl fermion gaugino $\lambda^a$. The index $a$ here runs over the adjoint representation of the gauge group ($a = 1, \ldots, 8$ for $SU(3)_C$ color gluons and gluinos; $a = 1, 2, 3$ for $SU(2)_L$ weak isospin; $a = 1$ for $U(1)_Y$ weak hypercharge). The gauge transformations of the vector supermultiplet fields are

$$\delta_{\text{gauge}} A^a_\mu = \partial_\mu \Lambda^a + g f^{abc} A^{b}_\mu \Lambda^c, \quad (3.55)$$

$$\delta_{\text{gauge}} \Lambda^a = g f^{abc} \Lambda^b \Lambda^c, \quad (3.56)$$

where $\Lambda^a$ is an infinitesimal gauge transformation parameter, $g$ is the gauge coupling, and $f^{abc}$ are the totally antisymmetric structure constants that define the gauge group. The special case of an Abelian group is obtained by just setting $f^{abc} = 0$; the corresponding gaugino is a gauge singlet in that case. The conventions are such that for QED, $A^a_\mu = (V, \vec{A})$ where $V$ and $\vec{A}$ are the usual electric potential and vector potential, with electric and magnetic fields given by $\vec{E} = -\vec{\nabla} V - \partial_0 \vec{A}$ and $\vec{B} = \vec{\nabla} \times \vec{A}$.

The on-shell degrees of freedom for $A^a_\mu$ and $\Lambda^a$ amount to two bosonic and two fermionic helicity states (for each $a$), as required by supersymmetry. However, off-shell $\Lambda^a$ consists of two complex, or four real, fermionic degrees of freedom, while $A^a_\mu$ only has three real bosonic degrees of freedom; one degree of freedom is removed by the inhomogeneous gauge transformation eq. (3.55). So, we will need
Table 3.2: Counting of real degrees of freedom for each gauge supermultiplet.

one real bosonic auxiliary field, traditionally called \(D^a\), in order for supersymmetry to be consistent off-shell. This field also transforms as an adjoint of the gauge group \([i.e., \text{like eq. (3.56)} with \(\lambda^a\) replaced by \(D^a\)]\) and satisfies \((D^a)^* = D^a\). Like the chiral auxiliary fields \(F_i\), the gauge auxiliary field \(D^a\) has dimensions of \([\text{mass}]^2\) and no kinetic term, so it can be eliminated on-shell using its algebraic equation of motion. The counting of degrees of freedom is summarized in Table 3.2.

Therefore, the Lagrangian density for a gauge supermultiplet ought to be

\[
\mathcal{L}_{\text{gauge}} = -\frac{1}{4} F^a_{\mu\nu} F^{\mu\nu a} - i\lambda^{\dagger a} \tilde{\sigma}^\mu D_\mu \lambda^a + \frac{1}{2} D^a D^a ,
\]

where

\[
F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + gf^{abc} A^b_\mu A^c_\nu
\]

is the usual Yang-Mills field strength, and

\[
D_\mu \lambda^a = \partial_\mu \lambda^a + gf^{abc} A^b_\mu \lambda^c
\]

is the covariant derivative of the gaugino field. To check that eq. (3.57) is really supersymmetric, one must specify the supersymmetry transformations of the fields. The forms of these follow from the requirements that they should be linear in the infinitesimal parameters \(\epsilon, \epsilon^\dagger\) with dimensions of \([\text{mass}]^{-1/2}\), that \(\delta A^a_\mu\) is real, and that \(\delta D^a\) should be real and proportional to the field equations for the gaugino, in analogy with the role of the auxiliary field \(F\) in the chiral supermultiplet case. Thus one can guess, up to multiplicative factors, that

\[
\delta A^a_\mu = \frac{1}{\sqrt{2}} (\epsilon^\dagger \tilde{\sigma}_\mu \lambda^a + \lambda^{\dagger a} \sigma_\mu \epsilon) ,
\]

\[
\delta \lambda^a_\mu = \frac{i}{2\sqrt{2}} (\sigma^\mu \tilde{\sigma}_\nu \epsilon_\alpha) F^a_{\nu\mu} + \frac{1}{\sqrt{2}} \epsilon_\alpha D^a ,
\]

\[
\delta D^a = \frac{i}{\sqrt{2}} (\epsilon^\dagger \tilde{\sigma}^\mu D_\mu \lambda^a - D_\mu \lambda^{\dagger a} \sigma^\mu \epsilon) .
\]

The factors of \(\sqrt{2}\) are chosen so that the action obtained by integrating \(\mathcal{L}_{\text{gauge}}\) is indeed invariant, and the phase of \(\lambda^a\) is chosen for future convenience in treating the MSSM.

It is now a little bit tedious, but straightforward, to also check that

\[
(\delta_{12} \delta_{\epsilon_1} - \delta_{\epsilon_1} \delta_{12}) X = i(\epsilon_1 \sigma^{\mu \dagger 1} - \epsilon_2 \sigma^{\mu \dagger 2}) D_\mu X
\]

for \(X\) equal to any of the gauge-covariant fields \(F^a_{\mu\nu}\), \(\lambda^a\), \(\lambda^{\dagger a}\), \(D^a\), as well as for arbitrary covariant derivatives acting on them. This ensures that the supersymmetry algebra eqs. (3.30)-(3.31) is realized

\footnote{The supersymmetry transformations eqs. (3.30)-(3.31) are non-linear for non-Abelian gauge symmetries, since there are gauge fields in the covariant derivatives acting on the gaugino fields and in the field strength \(F^a_{\mu\nu}\). By adding even more auxiliary fields besides \(D^a\), one can make the supersymmetry transformations linear in the fields. The version here, in which those extra auxiliary fields have been removed by gauge transformations, is called “Wess-Zumino gauge” \[52\].}
on gauge-invariant combinations of fields in gauge supermultiplets, as they were on the chiral supermul-
triplets [compare eq. (3.16)]. This check requires the use of identities eqs. (2.18), (2.20) and (2.23). If
we had not included the auxiliary field $D^a$, then the supersymmetry algebra eq. (3.3) would hold only
after using the equations of motion for $\lambda^a$ and $\lambda^a$. The auxiliary fields satisfies a trivial equation of
motion $D^a = 0$, but this is modified if one couples the gauge supermultiplets to chiral supermultiplets,
as we now do.

3.4 Supersymmetric gauge interactions

Finally we are ready to consider a general Lagrangian density for a supersymmetric theory with both
chiral and gauge supermultiplets. Suppose that the chiral supermultiplets transform under the gauge
channel with hermitian matrices $(T^a)_{ij}$ satisfying $[T^a, T^b] = i f^{abc}T^c$. [For example,
if the gauge group is $SU(2)$, then $f^{abc} = \epsilon^{abc}$, and the $T^a$ are 1/2 times the Pauli matrices for a
chiral supermultiplet transforming in the fundamental representation.] Since supersymmetry and gauge
transformations commute, the scalar, fermion, and auxiliary fields must be in the same representation
of the gauge group, so

$$\delta_{\text{gauge}} X_i = ig A^a (T^a X)_i$$

for $X_i = \phi_i, \psi_i, F_i$. To have a gauge-invariant Lagrangian, we now need to replace the ordinary
derivatives in eq. (3.3) with covariant derivatives:

$$\partial_i \phi_i \rightarrow D_i \phi_i = \partial_i \phi_i - ig A^a \mu (T^a \phi)_i$$
$$\partial_i \phi^i \rightarrow D_i \phi^i = \partial_i \phi^i + ig A^a \mu (\phi^i T^a)_i$$

Naively, this simple procedure achieves the goal of coupling the vector bosons in the gauge supermul-
tiplet to the scalars and fermions in the chiral supermultiplets. However, we also have to consider
whether there are any other interactions allowed by gauge invariance and involving the gaugino and
$D^a$ fields, which might have to be included to make a supersymmetric Lagrangian. Since $A^a$ couples
to $\phi_i$ and $\psi_i$, it makes sense that $\lambda^a$ and $D^a$ should as well.

In fact, there are three such possible interaction terms that are renormalizable (of field mass di-
4), namely

$$(\phi^i T^a \psi) \lambda^a, \quad (\psi^i T^a \phi) \lambda^a, \quad \text{and} \quad (\phi^i T^a \phi) D^a.$$

Now one can add them, with unknown dimensionless coupling coefficients, to the Lagrangians for
the chiral and gauge supermultiplets, and demand that the whole mess be real and invariant under supersymmetry, up to a total derivative. Not surprisingly, this is possible only if the supersymmetry
transformation laws for the matter fields are modified to include gauge-covariant rather than ordinary
derivatives. Also, it is necessary to include one strategically chosen extra term in $\delta F_i$, so:

$$\delta F_i = \epsilon^i \lambda^a.$$
Here $L_{\text{chiral}}$ means the chiral supermultiplet Lagrangian found in section 3.2 [e.g., eq. (3.49) or (3.51)], but with ordinary derivatives replaced everywhere by gauge-covariant derivatives, and $L_{\text{gauge}}$ was given in eq. (3.57). To prove that eq. (3.72) is invariant under the supersymmetry transformations, one must use the identity

$$W^i(T^a \phi)_i = 0. \tag{3.73}$$

This is precisely the condition that must be satisfied anyway in order for the superpotential, and thus $L_{\text{chiral}}$, to be gauge invariant, since the left side is proportional to $\delta_{\text{gauge}} W$.

The second line in eq. (3.72) consists of interactions whose strengths are fixed to be gauge couplings by the requirements of supersymmetry, even though they are not gauge interactions from the point of view of an ordinary field theory. The first two terms are a direct coupling of gauginos to matter fields; this can be thought of as the “supersymmetrization” of the usual gauge boson couplings to matter fields. The last term combines with the $D^a D^a/2$ term in $L_{\text{gauge}}$ to provide an equation of motion

$$D^a = -g(\phi^* T^a \phi). \tag{3.74}$$

Thus, like the auxiliary fields $F_i$ and $F^i$, the $D^a$ are expressible purely algebraically in terms of the scalar fields. Replacing the auxiliary fields in eq. (3.72) using eq. (3.74), one finds that the complete scalar potential is (recall that $L$ contains $-V$):

$$V(\phi, \phi^*) = F^i F_i + \frac{1}{2} \sum_a D^a D^a = W_i^* W_i + \frac{1}{2} \sum_a g_a^2 (\phi^* T^a \phi)^2. \tag{3.75}$$

The two types of terms in this expression are called “$F$-term” and “$D$-term” contributions, respectively. In the second term in eq. (3.75), we have now written an explicit sum $\sum_a$ to cover the case that the gauge group has several distinct factors with different gauge couplings $g_a$. [For instance, in the MSSM the three factors $SU(3)_C$, $SU(2)_L$ and $U(1)_Y$ have different gauge couplings $g_3$, $g$ and $g'$.] Since $V(\phi, \phi^*)$ is a sum of squares, it is always greater than or equal to zero for every field configuration. It is an interesting and unique feature of supersymmetric theories that the scalar potential is completely determined by the other interactions in the theory. The $F$-terms are fixed by Yukawa couplings and fermion mass terms, and the $D$-terms are fixed by the gauge interactions.

By using Noether’s procedure [see eq. (3.17)], one finds the conserved supercurrent

$$J^\mu_\alpha = (\sigma^\nu \sigma^\mu \psi_i)_\alpha D_\nu \phi^i - i(\sigma^\mu \psi^i)_\alpha W^i + \frac{1}{2} \sqrt{2} (\sigma^\nu \sigma^\mu \lambda^a)_\alpha F_{\mu \nu}^a - i g_0 \phi^* T^a \phi (\sigma^\mu \lambda^a)_\alpha, \tag{3.76}$$

generalizing the expression given in eq. (3.18) for the Wess-Zumino model. This result will be useful when we discuss certain aspects of spontaneous supersymmetry breaking in section 6.5.

### 3.5 Summary: How to build a supersymmetric model

In a renormalizable supersymmetric field theory, the interactions and masses of all particles are determined just by their gauge transformation properties and by the superpotential $W$. By construction, we found that $W$ had to be an analytic function of the complex scalar fields $\phi_i$, which are always defined to transform under supersymmetry into left-handed Weyl fermions. We should mention that in an equivalent language, $W$ is said to be a function of chiral superfields [50]. A superfield is a single object that contains as components all of the bosonic, fermionic, and auxiliary fields within the corresponding supermultiplet, for example $\Phi_i \supset (\phi_i, \psi_i, F_i)$. (This is analogous to the way in which one often describes a weak isospin doublet or color triplet by a multicomponent field.) The gauge quantum numbers and
the mass dimension of a chiral superfield are the same as that of its scalar component. In the superfield formulation, one writes instead of eq. (3.47)

$$W = L^i_i\Phi_i + \frac{1}{2}M^{ij}_i\Phi_i\Phi_j + \frac{1}{6}y^{ijk}\Phi_i\Phi_j\Phi_k,$$

which implies exactly the same physics. The derivation of all of our preceding results can be obtained somewhat more elegantly using superfield methods, which have the advantage of making invariance under supersymmetry transformations manifest by defining the Lagrangian in terms of integrals over a “superspace” with fermionic as well as ordinary commuting coordinates. We have avoided this extra layer of notation on purpose, in favor of the more pedestrian, but more familiar and accessible, component field approach. The latter is at least more appropriate for making contact with phenomenology in a universe with supersymmetry breaking. The only (occasional) use we will make of superfield notation is the purely cosmetic one of following the common practice of specifying superpotentials like eq. (3.77) rather than eq. (3.47). The specification of the superpotential is really a code for the terms that it implies in the Lagrangian, so the reader may feel free to think of the superpotential either as a function of the scalar fields $\phi_i$ or as the same function of the superfields $\Phi_i$.

Given the supermultiplet content of the theory, the form of the superpotential is restricted by the requirement of gauge invariance [see eq. (3.73)]. In any given theory, only a subset of the parameters $L^i_i$, $M^{ij}_i$, and $y^{ijk}$ are allowed to be non-zero. The parameter $L^i_i$ is only allowed if $\Phi_i$ is a gauge singlet. (There are no such chiral supermultiplets in the MSSM with the minimal field content.) The entries of the mass matrix $M^{ij}_i$ can only be non-zero for $i$ and $j$ such that the supermultiplets $\Phi_i$ and $\Phi_j$ transform under the gauge group in representations that are conjugates of each other. (In the MSSM there is only one such term, as we will see.) Likewise, the Yukawa couplings $y^{ijk}$ can only be non-zero when $\Phi_i$, $\Phi_j$, and $\Phi_k$ transform in representations that can combine to form a singlet. The interactions implied by the superpotential eq. (3.77) (with $L^i_i = 0$) were listed in eqs. (3.50), (3.51), and are shown† in Figures 3.1 and 3.2. Those in Figure 3.1 are all determined by the dimensionless parameters $y^{ijk}$. The Yukawa interaction in Figure 3.1a corresponds to the next-to-last term in eq. (3.51). For each particular Yukawa coupling of $\phi_j\psi_j\psi_k$ with strength $y^{ijk}$, there must be equal couplings of $\phi_j\psi_i\psi_k$, and $\phi_k\psi_i\psi_j$, since $y^{ijk}$ is completely symmetric under interchange of any two of its indices as shown in section 3.2. The arrows on the fermion and scalar lines point in the direction for propagation of $\phi$ and $\psi$ and opposite the direction of propagation of $\phi^*$ and $\psi^\dagger$. Thus there is also a vertex corresponding to the one in Figure 3.1a but with all arrows reversed, corresponding to the complex conjugate [the last term in eq. (3.51)]. It is shown in Figure 3.1b. There is also a dimensionless coupling for $\phi_i\phi_j\phi^*_k\phi^*_l$, with strength $y^{ijn}y_{kln}^*$, as required by supersymmetry [see the last term in eq. (3.50)]. The relationship between the Yukawa interactions in Figures 3.1a,b and the scalar interac-

---

†Here, the auxiliary fields have been eliminated using their equations of motion (“integrated out”). One could instead give Feynman rules that include the auxiliary fields, or directly in terms of superfields on superspace, although this is usually less useful in practical phenomenological applications.
Figure 3.2: Supersymmetric dimensionful couplings: (a) (scalar)$^3$ interaction vertex $M_{i}^{*}y_{jkn}$ and (b) the conjugate interaction $M^{in}y_{jkn}^{*}$, (c) fermion mass term $M^{ij}$ and (d) conjugate fermion mass term $M_{ij}^{*}$, and (e) scalar squared-mass term $M_{ik}^{*}M^{kj}$.

Figure 3.3: Supersymmetric gauge interaction vertices.

Figure 3.3: Supersymmetric gauge interaction vertices.
any of these three vertices may be obtained from any other (up to a factor of $\sqrt{2}$) by replacing two of the particles by their supersymmetric partners. There is also an interaction in Figure 3.3h which is just like Figure 3.3g but with all arrows reversed, corresponding to the complex conjugate term in the Lagrangian [the second term in the second line in eq. (3.72)]. Finally in Figure 3.3i we have a scalar quartic interaction vertex [the last term in eq. (3.75)], which is also determined by the gauge coupling.

The results of this section can be used as a recipe for constructing the supersymmetric interactions for any model. In the case of the MSSM, we already know the gauge group, particle content and the gauge transformation properties, so it only remains to decide on the superpotential. This we will do in section 5.1.

4 Soft supersymmetry breaking interactions

A realistic phenomenological model must contain supersymmetry breaking. From a theoretical perspective, we expect that supersymmetry, if it exists at all, should be an exact symmetry that is broken spontaneously. In other words, the underlying model should have a Lagrangian density that is invariant under supersymmetry, but a vacuum state that is not. In this way, supersymmetry is hidden at low energies in a manner analogous to the fate of the electroweak symmetry in the ordinary Standard Model.

Many models of spontaneous symmetry breaking have indeed been proposed and we will mention the basic ideas of some of them in section 6. These always involve extending the MSSM to include new particles and interactions at very high mass scales, and there is no consensus on exactly how this should be done. However, from a practical point of view, it is extremely useful to simply parameterize our ignorance of these issues by just introducing extra terms that break supersymmetry explicitly in the effective MSSM Lagrangian. As was argued in the Introduction, the supersymmetry-breaking couplings should be soft (of positive mass dimension) in order to be able to naturally maintain a hierarchy between the electroweak scale and the Planck (or any other very large) mass scale. This means in particular that dimensionless supersymmetry-breaking couplings should be absent.

The possible soft supersymmetry-breaking terms in the Lagrangian of a general theory are

$$L_{\text{soft}} = -\left(\frac{1}{2} M_a \lambda^a \lambda^a + \frac{1}{6} a^{ijk} \phi_i \phi_j \phi_k + \frac{1}{2} b^{ij} \phi_i \phi_j + t^i \phi_i \right) + c.c. - (m^2)^i_j \phi^i \phi^*_j, \quad (4.1)$$

$$L_{\text{maybe soft}} = -\frac{1}{2} c^{ijk}_i \phi^* i \phi_j \phi_k + c.c. \quad (4.2)$$

They consist of gaugino masses $M_a$ for each gauge group, scalar squared-mass terms $(m^2)^i_j$ and $b^{ij}$, and (scalar) $^3$ couplings $a^{ijk}$ and $c^{ijk}_i$, and “tadpole” couplings $t^i$. The last of these can only occur if $\phi_i$ is a gauge singlet, and so is absent from the MSSM. One might wonder why we have not included possible soft mass terms for the chiral supermultiplet fermions, like $L = -\frac{1}{2} m^{ij} \bar{\psi}_i \psi_j + c.c$. Including such terms would be redundant; they can always be absorbed into a redefinition of the superpotential and the terms $(m^2)^i_j$ and $c^{ik}_i$.

It has been shown rigorously that a softly broken supersymmetric theory with $L_{\text{soft}}$ as given by eq. (4.1) is indeed free of quadratic divergences in quantum corrections to scalar masses, to all orders in perturbation theory [53]. The situation is slightly more subtle if one tries to include the non-analytic (scalar) $^3$ couplings in $L_{\text{maybe soft}}$. If any of the chiral supermultiplets in the theory are singlets under all gauge symmetries, then non-zero $c^{ijk}_i$ terms can lead to quadratic divergences, despite the fact that they are formally soft. Now, this constraint need not apply to the MSSM, which does not have any gauge-singlet chiral supermultiplets. Nevertheless, the possibility of $c^{ijk}_i$ terms is nearly always neglected. The real reason for this is that it is extremely difficult to construct any model of spontaneous supersymmetry breaking in which the $c^{ijk}_i$ are not negligibly small. There are also possible fermion mass mixing terms
between gauginos and any chiral supermultiplets that happen to be in the adjoint representation of a simple factor of the gauge group $[54]$. Since this does not occur in the MSSM with minimal field content, I have neglected that possibility here for simplicity. Equation (4.1) is therefore usually taken to be the general form of the soft supersymmetry-breaking Lagrangian. (See, however, refs. $[54] - [56]$.)

Supersymmetry is indeed broken by $L_{\text{soft}}$, because it involves only scalars and gauginos and not their respective superpartners. In fact, the soft terms in $L_{\text{soft}}$ are capable of giving masses to all of the scalars and gauginos in a theory, even if the gauge bosons and fermions in chiral supermultiplets are massless (or relatively light). The gaugino masses $M_a$ are always allowed by gauge symmetry. The $(m^2)_{ij}$ terms are allowed for $i, j$ such that $\phi_i, \phi_j^*$ transform in complex conjugate representations of each other under all gauge symmetries; in particular this is true of course when $i = j$, so every scalar is eligible to get a mass in this way if supersymmetry is broken. The remaining soft terms may or may not be allowed by the symmetries. The $a^{ijk}$, $b^{ij}$, and $t^i$ terms have the same form as the $y^{ijk}$, $M^{ij}$, and $L^i$ terms in the superpotential [compare eq. (4.1) to eq. (3.47) or eq. (3.77)], so they will each be allowed by gauge invariance if and only if a corresponding superpotential term is allowed.

The Feynman diagram interactions corresponding to the allowed soft terms in eq. (4.1) are shown in Figure 4.1. For each of the interactions in Figures 4.1a,c,d there is another with all arrows reversed, corresponding to the complex conjugate term in the Lagrangian. We will apply these general results to the specific case of the MSSM in the next section.

## 5 The Minimal Supersymmetric Standard Model

In sections 3 and 4, we have found a general recipe for constructing Lagrangians for softly broken supersymmetric theories. We are now ready to apply these general results to the MSSM. The particle content for the MSSM was described in the Introduction. In this section we will complete the model by specifying the superpotential and the soft supersymmetry-breaking terms.

### 5.1 The superpotential and supersymmetric interactions

The superpotential for the MSSM is

$$W_{\text{MSSM}} = \overline{y}_u Q H_u - \overline{y}_d Q H_d - \overline{y}_e L H_d + \mu H_u H_d.$$  (5.1)

The objects $H_u$, $H_d$, $Q$, $L$, $\overline{u}$, $\overline{d}$, $\overline{e}$ appearing here are chiral superfields corresponding to the chiral supermultiplets in Table 1.1. (Alternatively, they can be just thought of as the corresponding scalar fields, as was done in section 3 but we prefer not to put the tildes on $Q$, $L$, $\overline{u}$, $\overline{d}$, $\overline{e}$ in order to reduce clutter.) The dimensionless Yukawa coupling parameters $y_u$, $y_d$, $y_e$ are 3×3 matrices in family space. All of the gauge $[SU(3)_C]$ color and $SU(2)_L$ weak isospin] and family indices in eq. (5.1) are suppressed. The “$\mu$ term”, as it is traditionally called, can be written out as $\mu(H_u)_{\alpha}(H_d)_{\beta}\epsilon^{\alpha\beta}$, where $\epsilon^{\alpha\beta}$ is used to tie together $SU(2)_L$ weak isospin indices $\alpha, \beta = 1, 2$ in a gauge-invariant way. Likewise, the term $\overline{y}_u Q H_u$ can be written out as $\overline{u}^a (y_u)^{ij} Q_{j\alpha} (H_u)_{\beta}\epsilon^{\alpha\beta}$, where $i = 1, 2, 3$ is a family index, and $a = 1, 2, 3$ is a color index which is lowered (raised) in the 3 (3) representation of $SU(3)_C$. 

30
The $\mu$ term in eq. (5.1) is the supersymmetric version of the Higgs boson mass in the Standard Model. It is unique, because terms $H_u^* H_u$ or $H_d^* H_d$ are forbidden in the superpotential, which must be analytic in the chiral superfields (or equivalently in the scalar fields) treated as complex variables, as shown in section 3.2. We can also see from the form of eq. (5.1) why both $H_u$ and $H_d$ are needed in order to give Yukawa couplings, and thus masses, to all of the quarks and leptons. Since the superpotential must be analytic, the $\bar{u} Q H_u$ Yukawa terms cannot be replaced by something like $\bar{u} Q H_d^*$. Similarly, the $\bar{d} Q H_d$ and $\bar{e} L H_d$ terms cannot be replaced by something like $\bar{d} Q H_u^*$ and $\bar{e} L H_u^*$. The analogous Yukawa couplings would be allowed in a general non-supersymmetric two Higgs doublet model, but are forbidden by the structure of supersymmetry. So we need both $H_u$ and $H_d$, even without invoking the argument based on anomaly cancellation mentioned in the Introduction.

The Yukawa matrices determine the current masses and CKM mixing angles of the ordinary quarks and leptons, after the neutral scalar components of $H_u$ and $H_d$ get VEVs. Since the top quark, bottom quark and tau lepton are the heaviest fermions in the Standard Model, it is often useful to make an approximation that only the $(3,3)$ family components of each of $y_u$, $y_d$ and $y_e$ are important:

$$
\begin{align*}
  y_u &\approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \\
  y_d &\approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \\
  y_e &\approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.
\end{align*}
$$

In this limit, only the third family and Higgs fields contribute to the MSSM superpotential. It is instructive to write the superpotential in terms of the separate $SU(2)_L$ weak isospin components $Q_3 = (t b), L_3 = (\nu \tau), H_u = (H_u^+ H_u^0), H_d = (H_d^0 H_d^-), \bar{u}_3 = \bar{u}, \bar{d}_3 = \bar{d}, \bar{e}_3 = \bar{\tau}$, so:

$$
W_{\text{MSSM}} \approx y_t(\bar{t}t H_u^0 - \bar{b}b H_u^+ - \bar{d}d H_d^- - \bar{e}e H_d^0) - y_\tau(\bar{\tau} \tau H_d^0 - \bar{\tau} \tau H_d^0) + \mu(H_u^+ H_u^- - H_d^0 H_d^0).
$$

The minus signs inside the parentheses appear because of the antisymmetry of the $\epsilon^{\alpha \beta}$ symbol used to tie up the $SU(2)_L$ indices. The other minus signs in eq. (5.1) were chosen so that the terms $y_t \bar{t} H_u^0$, $y_b \bar{b} H_u^0$, and $y_\tau \bar{\tau} H_d^0$, which will become the top, bottom and tau masses when $H_u^0$ and $H_d^0$ get VEVs, each have overall positive signs in eq. (5.3).

Since the Yukawa interactions $y_{ijk}$ in a general supersymmetric theory must be completely symmetric under interchange of $i, j, k$, we know that $y_u$, $y_d$ and $y_e$ imply not only Higgs-quark-quark and Higgs-lepton-lepton couplings as in the Standard Model, but also squark-Higgsino-squark and slepton-Higgsino-lepton interactions. To illustrate this, Figures 5.1a,b,c show some of the interactions involving the top-quark Yukawa coupling $y_t$. Figure 5.1a is the Standard Model-like coupling of the top quark to the neutral complex scalar Higgs boson, which follows from the first term in eq. (5.3). For variety, we have used $\bar{t}_L$ and $\bar{t}_R$ in place of their synonyms $t$ and $\bar{t}$ (see the discussion near the end of section 2). In Figure 5.1b, we have the coupling of the left-handed top squark $\tilde{t}_L$ to the neutral higgsino field $\tilde{H}_u^0$ and right-handed top quark, while in Figure 5.1c: the right-handed top anti-squark field (known either as $\bar{t}$ or $\tilde{t}_R$ depending on taste) couples to $\tilde{H}_u^0$ and $t_L$. For each of the three interactions, there is another with $\tilde{H}_u^0 \rightarrow H_u^+$ and $t_L \rightarrow -b_L$ (with tildes where appropriate), corresponding to the second

---

**Figure 5.1:** The top-quark Yukawa coupling (a) and its “supersymmetrizations” (b), (c), all of strength $y_t$.
part of the first term in eq. (5.3). All of these interactions are required by supersymmetry to have the same strength \( y_t \). These couplings are dimensionless and can be modified by the introduction of soft supersymmetry breaking only through finite (and small) radiative corrections, so this equality of interaction strengths is also a prediction of softly broken supersymmetry. A useful mnemonic is that each of Figures 5.1a,b,c can be obtained from any of the others by changing two of the particles into their superpartners.

There are also scalar quartic interactions with strength proportional to \( y_t^2 \), as can be seen from Figure 5.3 or the last term in eq. (3.50). Three of them are shown in Figure 5.2. Using eq. (3.50) and eq. (5.3), one can see that there are five more, which can be obtained by replacing \( \tilde{t}_L \rightarrow \tilde{b}_L \) and/or \( H^0_u \rightarrow H^+_u \) in each vertex. This illustrates the remarkable economy of supersymmetry; there are many interactions determined by only a single parameter. In a similar way, the existence of all the other quark and lepton Yukawa couplings in the superpotential eq. (5.1) leads not only to Higgs-quark-quark and Higgs-lepton-lepton Lagrangian terms as in the ordinary Standard Model, but also to squark-higgsino-quark and slepton-higgsino-lepton terms, and scalar quartic couplings \([\text{squark}]^4\), \([\text{slepton}]^4\), \([\text{squark}]^2\text{(slepton)}^2\), \([\text{squark}]^2\text{(Higgs)}^2\), and \([\text{slepton}]^2\text{(Higgs)}^2\). If needed, these can all be obtained in terms of the Yukawa matrices \( y_u \), \( y_d \), and \( y_e \) as outlined above.

However, the dimensionless interactions determined by the superpotential are usually not the most important ones of direct interest for phenomenology. This is because the Yukawa couplings are already known to be very small, except for those of the third family (top, bottom, tau). Instead, production and decay processes for superpartners in the MSSM are typically dominated by the supersymmetric interactions of gauge-coupling strength, as we will explore in more detail in sections \[\boxed{3}\] and \[\boxed{9}\]. The couplings of the Standard Model gauge bosons (photon, \( W^\pm \), \( Z^0 \) and gluons) to the MSSM particles are determined completely by the gauge invariance of the kinetic terms in the Lagrangian. The gauginos also couple to (squark, quark) and (slepton, lepton) and (Higgs, higgsino) pairs as illustrated in the general case in Figure 3.3g,h and the first two terms in the second line in eq. (3.72). For instance, each of the squark-quark-gluino couplings is given by \( \sqrt{2}g_3(\bar{q}T^aq\tilde{g} + \text{c.c.}) \) where \( T^a = \lambda^a/2 \) (\( a = 1 \ldots 8 \)) are the matrix generators for \( SU(3)_C \). The Feynman diagram for this interaction is shown in Figure 5.3a. In Figures 5.3b,c we show in a similar way the couplings of (squark, quark), (lepton, slepton) and (Higgs, higgsino) pairs to the winos and bino, with strengths proportional to the electroweak gauge couplings \( g \) and \( g' \) respectively. For each of these diagrams, there is another with all arrows reversed. Note that the winos only couple to the left-handed squarks and sleptons, and the (lepton, slepton) and (Higgs, higgsino) pairs of course do not couple to the gluino. The bino coupling to each (scalar,
fermion) pair is also proportional to the weak hypercharge $Y$ as given in Table 1.1. The interactions shown in Figure 5.2 provide, for example, for decays $\tilde{q} \rightarrow q\tilde{g}$ and $\tilde{q} \rightarrow \tilde{W}^0 q'$ and $\tilde{q} \rightarrow \tilde{B} q$ when the final states are kinematically allowed to be on-shell. However, a complication is that the $\tilde{W}$ and $\tilde{B}$ states are not mass eigenstates, because of splitting and mixing due to electroweak symmetry breaking, as we will see in section 7.2.

There are also various scalar quartic interactions in the MSSM that are uniquely determined by gauge invariance and supersymmetry, according to the last term in eq. (3.75), as illustrated in Figure 3.3. Among them are (Higgs)$^4$ terms proportional to $g^2$ and $\tilde{g}^2$ in the scalar potential. These are the direct generalization of the last term in the Standard Model Higgs potential, eq. (1.1), to the case of the MSSM. We will have occasion to identify them explicitly when we discuss the minimization of the MSSM Higgs potential in section 7.3.

The dimensionful couplings in the supersymmetric part of the MSSM Lagrangian are all dependent on $\mu$. Using the general result of eq. (3.51), $\mu$ provides for higgsino fermion mass terms

$$-\mathcal{L}_{\text{higgsino mass}} = \mu (\tilde{H}_u^+ \tilde{H}_d^- - \tilde{H}_u^0 \tilde{H}_d^0) + \text{c.c.},$$

as well as Higgs squared-mass terms in the scalar potential

$$-\mathcal{L}_{\text{supersymmetric Higgs mass}} = |\mu|^2 (|H_u^0|^2 + |H_u^+|^2 + |H_d^0|^2 + |H_d^-|^2).$$

Since eq. (5.5) is non-negative with a minimum at $H_u^0 = H_d^0 = 0$, we cannot understand electroweak symmetry breaking without including a negative supersymmetry-breaking squared-mass soft term for the Higgs scalars. An explicit treatment of the Higgs scalar potential will therefore have to wait until we have introduced the soft terms for the MSSM. However, we can already see a puzzle: we expect that $\mu$ should be roughly of order $10^2$ or $10^3$ GeV, in order to allow a Higgs VEV of order 174 GeV without too much miraculous cancellation between $|\mu|^2$ and the negative soft squared-mass terms that we have not written down yet. But why should $|\mu|^2$ be so small compared to, say, $M^2_P$, and in particular why should it be roughly of the same order as $m^2_{\text{soft}}$? The scalar potential of the MSSM seems to depend on two types of dimensionful parameters that are conceptually quite distinct, namely the supersymmetry-respecting mass $\mu$ and the supersymmetry-breaking soft mass terms. Yet the observed value for the electroweak breaking scale suggests that without miraculous cancellations, both of these apparently unrelated mass scales should be within an order of magnitude or so of 100 GeV. This puzzle is called “the $\mu$ problem”. Several different solutions to the $\mu$ problem have been proposed, involving extensions of the MSSM of varying intricacy. They all work in roughly the same way: the $\mu$ term is required or assumed to be absent at tree-level before symmetry breaking, and then it arises from the VEV(s) of some new field(s). These VEVs are in turn determined by minimizing a potential that depends on soft supersymmetry-breaking terms. In this way, the value of the effective parameter $\mu$ is no longer conceptually distinct from the mechanism of supersymmetry breaking; if we can explain why $m_{\text{soft}} \ll M_P$, we will also be able to understand why $\mu$ is of the same order. In section 10.2 we will study one such mechanism. Some other attractive solutions for the $\mu$ problem are proposed in refs. 57-59. From the point of view of the MSSM, however, we can just treat $\mu$ as an independent parameter.

The $\mu$-term and the Yukawa couplings in the superpotential eq. (5.1) combine to yield (scalar)$^3$ couplings [see the second and third terms on the right-hand side of eq. (3.50)] of the form

$$\mathcal{L}_{\text{supersymmetric (scalar)$^3$}} = \mu^* (\overline{\nu}_u \tilde{u} H_d^0 + \overline{d}_u \tilde{d} H_u^0 + \overline{\nu}_e \tilde{e} H_u^0 + \overline{\nu}_d \tilde{d} H_d^0 + \overline{\nu}_u \tilde{u} H_u^+ + \overline{\nu}_e \tilde{e} H_u^+) + \text{c.c.}$$

Figure 5.4 shows some of these couplings, proportional to $\mu^* y_t$, $\mu^* y_b$, and $\mu^* y_{\tau}$ respectively. These play an important role in determining the mixing of top squarks, bottom squarks, and tau sleptons, as we will see in section 7.4.
5.2 \( R \)-parity (also known as matter parity) and its consequences

The superpotential eq. (5.1) is minimal in the sense that it is sufficient to produce a phenomenologically viable model. However, there are other terms that one can write that are gauge-invariant and analytic in the chiral superfields, but are not included in the MSSM because they violate either baryon number (B) or total lepton number (L). The most general gauge-invariant and renormalizable superpotential would include not only eq. (5.1), but also the terms

\[
W_{\Delta L=1} = \frac{1}{2} \lambda^{ij} L_i \bar{L}_j \overline{e}_k + \lambda^{ijk} L_i \bar{Q}_j \overline{d}_k + \mu^i \overline{L}_i H_u
\]

(5.7)

\[
W_{\Delta B=1} = \frac{1}{2} \lambda^{ij} \overline{u}_i \overline{d}_j \overline{d}_k
\]

(5.8)

where family indices \( i = 1, 2, 3 \) have been restored. The chiral supermultiplets carry baryon number assignments \( B = +1/3 \) for \( Q_i \); \( B = -1/3 \) for \( \overline{u}_i, \overline{d}_i \); and \( B = 0 \) for all others. The total lepton number assignments are \( L = +1 \) for \( L_i \), \( L = -1 \) for \( \overline{e}_i \), and \( L = 0 \) for all others. Therefore, the terms in eq. (5.7) violate total lepton number by 1 unit (as well as the individual lepton flavors) and those in eq. (5.8) violate baryon number by 1 unit.

The possible existence of such terms might seem rather disturbing, since corresponding B- and L-violating processes have not been seen experimentally. The most obvious experimental constraint comes from the non-observation of proton decay, which would violate both B and L by 1 unit. If both \( \lambda^i \) and \( \lambda''^i \) couplings were present and unsuppressed, then the lifetime of the proton would be extremely short. For example, Feynman diagrams like the one in Figure 5.5 would lead to \( p^+ \rightarrow e^+ \pi^0 \) (shown) or \( e^+K^0 \) or \( \mu^+\pi^0 \) or \( \mu^+K^0 \) or \( \nu\pi^+ \) or \( \nu K^+ \) etc. depending on which components of \( \lambda' \) and \( \lambda'' \) are largest.\(^1\)

As a rough estimate based on dimensional analysis, for example,

\[
\Gamma_{p^+ \rightarrow e^+ \pi^0} \sim m_{p}^5 \sum_{i=2,3} |\lambda'^{1i1i2}/m_{d_i}^4|
\]

(5.9)

which would be a tiny fraction of a second if the couplings were of order unity and the squarks have masses of order 1 TeV. In contrast, the decay time of the proton into lepton+meson final states is

\(^1\)In this diagram and others below, the arrows on propagators are often omitted for simplicity, and external fermion label refer to physical particle states rather than 2-component fermion fields.

\(^2\)The coupling \( \lambda''^i \) must be antisymmetric in its last two flavor indices, since the color indices are combined antisymmetrically. That is why the squark in Figure 5.5 can be \( \tilde{s} \) or \( \tilde{b} \), but not \( \tilde{d} \), for \( u, d \) quarks in the proton.
known experimentally to be in excess of $10^{32}$ years. Therefore, at least one of $\lambda_{ijk}^\prime$ or $\lambda_{11k}^\prime\prime$ for each of $i = 1, 2; j = 1, 2; k = 2, 3$ must be extremely small. Many other processes also give strong constraints on the violation of lepton and baryon numbers [60, 61].

One could simply try to take B and L conservation as a postulate in the MSSM. However, this is clearly a step backward from the situation in the Standard Model, where the conservation of these quantum numbers is not assumed, but is rather a pleasantly “accidental” consequence of the fact that there are no possible renormalizable Lagrangian terms that violate B or L. Furthermore, there is a quite general obstacle to treating B and L as fundamental symmetries of Nature, since they are known to be necessarily violated by non-perturbative electroweak effects [62] (even though those effects are calculably negligible for experiments at ordinary energies). Therefore, in the MSSM one adds a new symmetry, which has the effect of eliminating the possibility of B and L violating terms in the renormalizable superpotential, while allowing the good terms in eq. (5.1). This new symmetry is called “R-parity” [7] or equivalently “matter parity” [63].

Matter parity is a multiplicatively conserved quantum number defined as

$$P_M = (-1)^{3(B-L)} \tag{5.10}$$

for each particle in the theory. It is easy to check that the quark and lepton supermultiplets all have $P_M = -1$, while the Higgs supermultiplets $H_u$ and $H_d$ have $P_M = +1$. The gauge bosons and gauginos of course do not carry baryon number or lepton number, so they are assigned matter parity $P_M = +1$. The symmetry principle to be enforced is that a candidate term in the Lagrangian (or in the superpotential) is allowed only if the product of $P_M$ for all of the fields in it is +1. It is easy to see that each of the terms in eqs. (5.7) and (5.8) is thus forbidden, while the good and necessary terms in eq. (5.1) are allowed. This discrete symmetry commutes with supersymmetry, as all members of a given supermultiplet have the same matter parity. The advantage of matter parity is that it can in principle be an exact and fundamental symmetry, which B and L themselves cannot, since they are known to be violated by non-perturbative electroweak effects. So even with exact matter parity conservation in the MSSM, one expects that baryon number and total lepton number violation can occur in tiny amounts, due to non-renormalizable terms in the Lagrangian. However, the MSSM does not have renormalizable interactions that violate B or L, with the standard assumption of matter parity conservation.

It is often useful to recast matter parity in terms of R-parity, defined for each particle as

$$P_R = (-1)^{3(B-L)+2s} \tag{5.11}$$

where $s$ is the spin of the particle. Now, matter parity conservation and R-parity conservation are precisely equivalent, since the product of $(-1)^{2s}$ for the particles involved in any interaction vertex in a theory that conserves angular momentum is always equal to +1. However, particles within the same supermultiplet do not have the same R-parity. In general, symmetries with the property that fields within the same supermultiplet have different transformations are called R-symmetries; they do not commute with supersymmetry. Continuous $U(1)$ R symmetries are often encountered in the model-building literature; they should not be confused with R-parity, which is a discrete $Z_2$ symmetry. In fact, the matter parity version of R-parity makes clear that there is really nothing intrinsically “R” about it; in other words it secretly does commute with supersymmetry, so its name is somewhat suboptimal. Nevertheless, the R-parity assignment is very useful for phenomenology because all of the Standard Model particles and the Higgs bosons have even R-parity ($P_R = +1$), while all of the squarks, sleptons, gauginos, and higgsinos have odd R-parity ($P_R = -1$).

The R-parity odd particles are known as “supersymmetric particles” or “sparticles” for short, and they are distinguished by a tilde (see Tables 1.1 and 1.2). If R-parity is exactly conserved, then there can be no mixing between the sparticles and the $P_R = +1$ particles. Furthermore, every interaction vertex in the theory contains an even number of $P_R = -1$ sparticles. This has three extremely important phenomenological consequences:
• The lightest sparticle with $P_R = -1$, called the “lightest supersymmetric particle” or LSP, must be absolutely stable. If the LSP is electrically neutral, it interacts only weakly with ordinary matter, and so can make an attractive candidate \[^{[64]}\] for the non-baryonic dark matter that seems to be required by cosmology.

• Each sparticle other than the LSP must eventually decay into a state that contains an odd number of LSPs (usually just one).

• In collider experiments, sparticles can only be produced in even numbers (usually two-at-a-time).

We define the MSSM to conserve $R$-parity or equivalently matter parity. While this decision seems to be well-motivated phenomenologically by proton decay constraints and the hope that the LSP will provide a good dark matter candidate, it might appear somewhat artificial from a theoretical point of view. After all, the MSSM would not suffer any internal inconsistency if we did not impose matter parity conservation. Furthermore, it is fair to ask why matter parity should be exactly conserved, given that the discrete symmetries in the Standard Model (ordinary parity $P$, charge conjugation $C$, time reversal $T$, etc.) are all known to be inexact symmetries. Fortunately, it is sensible to formulate matter parity as a discrete symmetry that is exactly conserved. In general, exactly conserved, or “gauged” discrete symmetries \[^{[65]}\] can exist provided that they satisfy certain anomaly cancellation conditions \[^{[66]}\] (much like continuous gauged symmetries). One particularly attractive way this could occur is if $B-L$ is a continuous gauge symmetry that is spontaneously broken at some very high energy scale. A continuous $U(1)_{B-L}$ forbids the renormalizable terms that violate $B$ and $L$ \[^{[67, 68]}\], but this gauge symmetry must be spontaneously broken, since there is no corresponding massless vector boson. However, if gauged $U(1)_{B-L}$ is only broken by scalar VEVs (or other order parameters) that carry even integer values of $3(B-L)$, then $P_M$ will automatically survive as an exactly conserved discrete remnant subgroup \[^{[68]}\]. A variety of extensions of the MSSM in which exact $R$-parity conservation is guaranteed in just this way have been proposed (see for example \[^{[68, 69]}\]).

It may also be possible to have gauged discrete symmetries that do not owe their exact conservation to an underlying continuous gauged symmetry, but rather to some other structure such as can occur in string theory. It is also possible that $R$-parity is broken, or is replaced by some alternative discrete symmetry. We will briefly consider these as variations on the MSSM in section \[^{[10.1]}\].

### 5.3 Soft supersymmetry breaking in the MSSM

To complete the description of the MSSM, we need to specify the soft supersymmetry breaking terms. In section \[^{[4]}\] we learned how to write down the most general set of such terms in any supersymmetric theory. Applying this recipe to the MSSM, we have:

$$\mathcal{L}_{\text{soft}}^{\text{MSSM}} = -\frac{1}{2} \left( M_3 \bar{g} g + M_2 \bar{W} W + M_1 \bar{B} \bar{B} + \text{c.c.} \right)$$

$$- \left( \bar{u} u + \bar{d} d + \bar{e} e \right) + \bar{Q} Q + \tilde{L} L + \bar{L} \tilde{L} + \bar{u} m_u^2 \bar{u} u + \bar{d} m_d^2 \bar{d} d + \bar{e} m_e^2 \bar{e} e$$

$$- m_{H_u}^2 H_u^* H_u - m_{H_d}^2 H_d^* H_d - (b H_u H_d + \text{c.c.}) \right).$$

(5.12)

In eq. (5.12), $M_3$, $M_2$, and $M_1$ are the gluino, wino, and bino mass terms. Here, and from now on, we suppress the adjoint representation gauge indices on the wino and gluino fields, and the gauge indices on all of the chiral supermultiplet fields. The second line in eq. (5.12) contains the (scalar)\(^3\) couplings [of the type $a_{ijk}^\alpha$ in eq. (1.1)]. Each of $a_u$, $a_d$, $a_e$ is a complex $3 \times 3$ matrix in family space, with dimensions of [mass]. They are in one-to-one correspondence with the Yukawa couplings of the superpotential. The third line of eq. (5.12) consists of squark and slepton mass terms of the $(m_i^2)$ type.
Figure 5.6: Some of the diagrams that contribute to the process $\mu^- \rightarrow e^- \gamma$ in models with lepton flavor-violating soft supersymmetry breaking parameters (indicated by $\times$). Diagrams (a), (b), and (c) contribute to constraints on the off-diagonal elements of $m^2_e$, $m^2_L$, and $a_e$, respectively.

in eq. (4.11). Each of $m^2_Q$, $m^2_u$, $m^2_d$, $m^2_e$, $m^2_\nu$ is a $3 \times 3$ matrix in family space that can have complex entries, but they must be hermitian so that the Lagrangian is real. (To avoid clutter, we do not put tildes on the $Q$ in $m^2_Q$, etc.) Finally, in the last line of eq. (5.12) we have supersymmetry-breaking contributions to the Higgs potential; $m^2_{H_u}$ and $m^2_{H_d}$ are squared-mass terms of the $(m^2)^i_j$ type, while $b$ is the only squared-mass term of the type $b^{ij}$ in eq. (4.1) that can occur in the MSSM. As argued in the Introduction, we expect

$$M_1, M_2, M_3, a_u, a_d, a_e \sim m_{\text{soft}},$$

$$m^2_Q, m^2_u, m^2_d, m^2_e, m^2_{H_u}, m^2_{H_d}, b \sim m^2_{\text{soft}},$$

(5.13) (5.14)

with a characteristic mass scale $m_{\text{soft}}$ that is not much larger than 1000 GeV. The expression eq. (5.12) is the most general soft supersymmetry-breaking Lagrangian of the form eq. (4.1) that is compatible with gauge invariance and matter parity conservation in the MSSM.

Unlike the supersymmetry-preserving part of the Lagrangian, the above $\mathcal{L}^{\text{MSSM}}_{\text{soft}}$ introduces many new parameters that were not present in the ordinary Standard Model. A careful count [70] reveals that there are 105 masses, phases and mixing angles in the MSSM Lagrangian that cannot be rotated away by redefining the phases and flavor basis for the quark and lepton supermultiplets, and that have no counterpart in the ordinary Standard Model. Thus, in principle, supersymmetry breaking (as opposed to supersymmetry itself) appears to introduce a tremendous arbitrariness in the Lagrangian.

5.4 Hints of an Organizing Principle

Fortunately, there is already good experimental evidence that some powerful organizing principle must govern the soft supersymmetry breaking Lagrangian. This is because most of the new parameters in eq. (5.12) imply flavor mixing or CP violating processes of the types that are severely restricted by experiment [71]-[96].

For example, suppose that $m^2_e$ is not diagonal in the basis $(\tilde{e}_R, \tilde{\mu}_R, \tilde{\tau}_R)$ of sleptons whose superpartners are the right-handed parts of the Standard Model mass eigenstates $e, \mu, \tau$. In that case, slepton mixing occurs, so the individual lepton numbers will not be conserved, even for processes that only involve the sleptons as virtual particles. A particularly strong limit on this possibility comes from the experimental bound on the process $\mu^- \rightarrow e^- \gamma$, which could arise from the one-loop diagram shown in Figure 5.6a. The symbol “$\times$” on the slepton line represents an insertion coming from $-(m^2_{e21})\tilde{\mu}_R\tilde{e}_R$ in $\mathcal{L}^{\text{soft}}$, and the slepton-bino vertices are determined by the weak hypercharge gauge coupling [see Figures 3.3g,h and eq. (3.72)]. The result of calculating this diagram gives $\mathcal{L}^{\text{MSSM}}_{\text{soft}}$, approximately,

$\text{The parameter called } b \text{ here is often seen elsewhere as } B_\mu \text{ or } m^2_{12} \text{ or } m^2_3.$
Figure 5.7: Some of the diagrams that contribute to $K^0 \leftrightarrow \overline{K}^0$ mixing in models with strangeness-violating soft supersymmetry breaking parameters (indicated by $\times$). These diagrams contribute to constraints on the off-diagonal elements of (a) $m^2_{\tilde{d}}$, (b) the combination of $m^2_{\tilde{d}}$ and $m^2_{\tilde{Q}}$, and (c) $a_d$.

\[
\text{Br}(\mu \to e\gamma) = \left(\frac{|m_{\tilde{d}R}^2|^2}{m_{\tilde{\mu}_R}^2}\right) \left(\frac{100 \text{ GeV}}{m_{\tilde{\mu}_R}}\right)^4 \times \begin{cases} 15 & \text{for } m_{\tilde{B}} < m_{\tilde{\mu}_R}, \\ 5.6 & \text{for } m_{\tilde{B}} = 0.5 m_{\tilde{\mu}_R}, \\ 1.4 & \text{for } m_{\tilde{B}} = m_{\tilde{\mu}_R}, \\ 0.13 & \text{for } m_{\tilde{B}} = 2 m_{\tilde{\mu}_R}, \end{cases}
\]

where it is assumed for simplicity that both $\tilde{\mu}_R$ and $\tilde{\mu}_R$ are nearly mass eigenstates with almost degenerate squared masses $m_{\tilde{\mu}_R}^2$, that $m_{\tilde{d}R}^2 \equiv (m_{\tilde{d}R})^2 = (m_{\tilde{d}L})^2$ can be treated as a perturbation, and that the bino $\tilde{B}$ is nearly a mass eigenstate. This result is to be compared to the present experimental upper limit $\text{Br}(\mu \to e\gamma)_{\text{exp}} < 1.2 \times 10^{-11}$ from [27]. So, if the right-handed slepton squared-mass matrix $m^2_{\tilde{L}}$ were “random”, with all entries of comparable size, then the prediction for $\text{Br}(\mu \to e\gamma)$ would be too large even if the sleptons and bino masses were at 1 TeV. For lighter superpartners, the constraint on $\tilde{\mu}_R, \tilde{\mu}_R$ squared-mass mixing becomes correspondingly more severe. There are also contributions to $\mu \to e\gamma$ that depend on the off-diagonal elements of the left-handed slepton squared-mass matrix $m^2_{\tilde{L}}$, coming from the diagram shown in fig. 5.6 involving the charged wino and the sneutrinos, as well as diagrams just like fig. 5.6, but with left-handed sleptons and either $B$ or $W^0$ exchanged. Therefore, the slepton squared-mass matrices must not have significant mixings for $\tilde{e}_L, \tilde{\mu}_L$ either.

Furthermore, after the Higgs scalars get VEVs, the $a_e$ matrix could imply squared-mass terms that mix left-handed and right-handed sleptons with different lepton flavors. For example, $L_{\text{MSSM}}$ contains $\bar{\tau} a_e L H_d + \text{c.c.}$ which implies terms $-\langle H_d^0 \rangle (a_e)_{12} \tilde{\tau}_R \tilde{\mu}_L - \langle H_d^0 \rangle (a_e)_{21} \tilde{\mu}_R \tilde{\tau}_L + \text{c.c.}$ These also contribute to $\mu \to e\gamma$, as illustrated in fig. 5.6. So the magnitudes of $(a_e)_{12}$ and $(a_e)_{21}$ are also constrained by experiment to be small, but in a way that is more strongly dependent on other model parameters. Similarly, $(a_e)_{13}, (a_e)_{31}$ and $(a_e)_{23}, (a_e)_{32}$ are constrained, although more weakly by 77, by the experimental limits on $\text{Br}(\tau \to e\gamma)$ and $\text{Br}(\tau \to \mu\gamma)$.

There are also important experimental constraints on the squark squared-mass matrices. The strongest of these come from the neutral kaon system. The effective Hamiltonian for $K^0 \leftrightarrow \overline{K}^0$ mixing gets contributions from the diagrams in Figure 5.7 among others, if $L_{\text{MSSM}}$ contains terms that mix down squarks and strange squarks. The gluino-squark-quark vertices in Figure 5.7 are all fixed by supersymmetry to be of QCD interaction strength. (There are similar diagrams in which the bino and winos are exchanged, which can be important depending on the relative sizes of the gaugino masses.) For example, suppose that there is a non-zero right-handed down-squark-squared-mass mixing $(m^2_{\tilde{d}})_{21}$ in the basis corresponding to the quark mass eigenstates. Assuming that the supersymmetric correction to $\Delta m_K \equiv m_{K_L} - m_{K_S}$ following from fig. 5.7, and others does not exceed, in absolute value, the experimental value $3.5 \times 10^{-12}$ MeV, ref. 80 obtains:

\[
\frac{|\text{Re}[(m_{\tilde{d}_R}^2)_{21}]|^2}{m_{\tilde{\mu}}^2} < \left(\frac{m_{\tilde{\mu}}}{500 \text{ GeV}}\right) \times \begin{cases} 0.02 & \text{for } m_{\tilde{\mu}} = 0.5 m_{\tilde{\mu}}, \\ 0.05 & \text{for } m_{\tilde{\mu}} = m_{\tilde{\mu}}, \\ 0.11 & \text{for } m_{\tilde{\mu}} = 2 m_{\tilde{\mu}}. \end{cases}
\]
Here nearly degenerate squarks with mass $m_{\tilde{q}}$ are assumed for simplicity, with $m_{\tilde{q}}^2_{\tilde{d}R} = (m_{\tilde{d}}^2)^{21}_{21}$ treated as a perturbation. The same limit applies when $m_{\tilde{q}}^2_{\tilde{d}L}$ is replaced by $m_{\tilde{q}}^2_{\tilde{d}L} = (m_{\tilde{Q}}^2)^{21}_{21}$, in a basis corresponding to the down-type quark mass eigenstates. An even more striking limit applies to the combination of both types of flavor mixing when they are comparable in size, from diagrams including fig. 5.7. The numerical constraint is [86]:

$$|\text{Re}[m_{\tilde{d}R}^2 m_{\tilde{d}L}^2]/m_{\tilde{q}}^2]|^{1/2} < \left( \frac{m_{\tilde{q}}}{500 \text{ GeV}} \right) \times \begin{cases} 0.0008 & \text{for } m_{\tilde{q}} = 0.5m_{\tilde{q}}, \\ 0.0010 & \text{for } m_{\tilde{q}} = m_{\tilde{q}}, \\ 0.0013 & \text{for } m_{\tilde{q}} = 2m_{\tilde{q}}. \end{cases} \quad (5.17)$$

An off-diagonal contribution from $a_d$ would cause flavor mixing between left-handed and right-handed squarks, just as discussed above for sleptons, resulting in a strong constraint from diagrams like fig. 5.7. More generally, limits on $\Delta m_K$ and $\epsilon$ and $\epsilon'/\epsilon$ appearing in the neutral kaon effective Hamiltonian severely restrict the amounts of $\tilde{d}_{L,R}$, $\tilde{s}_{L,R}$ squark mixings (separately and in various combinations), and associated CP-violating complex phases, that one can tolerate in the soft squared masses.

Weaker, but still interesting, constraints come from the $D^0, \bar{D}^0$ system, which limits the amounts of $\tilde{u}, \tilde{c}$ mixings from $m_{\tilde{u}}^2, m_{\tilde{c}}^2$ and $a_u$. The $B^0, \bar{B}^0$ and $B^0_s, \bar{B}^0_s$ systems similarly limit the amounts of $\tilde{d}, \tilde{b}$ and $\tilde{s}, \tilde{b}$ squark mixings from soft supersymmetry-breaking sources. More constraints follow from rare $\Delta F = 1$ meson decays, notably those involving the parton-level processes $b \rightarrow s\gamma$ and $b \rightarrow s\ell^+\ell^-$ and $c \rightarrow u\ell^+\ell^-$ and $s \rightarrow d\ell^+\ell^-$ and $s \rightarrow d\nu\bar{\nu}$, all of which can be mediated by flavor mixing in soft supersymmetry breaking. There are also strict constraints on CP-violating phases in the gaugino masses and (scalar)$^3$ soft couplings following from limits on the electric dipole moments of the neutron and electron [74]. Detailed limits can be found in the literature [71]-[96], but the essential lesson from experiment is that the soft supersymmetry-breaking Lagrangian cannot be arbitrary or random.

All of these potentially dangerous flavor-changing and CP-violating effects in the MSSM can be evaded if one assumes (or can explain!) that supersymmetry breaking is suitably “universal”. Consider an idealized limit in which the squark and slepton squared-mass matrices are flavor-blind, each proportional to the $3 \times 3$ identity matrix in family space:

$$m_{\tilde{Q}}^2 = m_{\tilde{Q}}^2 1, \quad m_{\tilde{u}}^2 = m_{\tilde{u}}^2 1, \quad m_{\tilde{d}}^2 = m_{\tilde{d}}^2 1, \quad m_{\tilde{l}}^2 = m_{\tilde{l}}^2 1, \quad m_{\tilde{e}}^2 = m_{\tilde{e}}^2 1. \quad (5.18)$$

Then all squark and slepton mixing angles are rendered trivial, because squarks and sleptons with the same electroweak quantum numbers will be degenerate in mass and can be rotated into each other at will. Supersymmetric contributions to flavor-changing neutral current processes will therefore be very small in such an idealized limit, up to mixing induced by $a_u, a_d, a_e$. Making the further assumption that the (scalar)$^3$ couplings are each proportional to the corresponding Yukawa coupling matrix,

$$a_u = A_{u0} y_u, \quad a_d = A_{d0} y_d, \quad a_e = A_{e0} y_e, \quad (5.19)$$

will ensure that only the squarks and sleptons of the third family can have large (scalar)$^3$ couplings. Finally, one can avoid disastrously large CP-violating effects by assuming that the soft parameters do not introduce new complex phases. This is automatic for $m_{\tilde{H}_u}^2$ and $m_{\tilde{H}_d}^2$, and for $m_{\tilde{Q}}^2, m_{\tilde{F}}^2$ etc. if eq. (5.18) is assumed; if they were not real numbers, the Lagrangian would not be real. One can also fix $\mu$ in the superpotential and $b$ in eq. (5.12) to be real, by appropriate phase rotations of fermion and scalar components of the $H_u$ and $H_d$ supermultiplets. If one then assumes that

$$\text{arg}(M_1), \text{arg}(M_2), \text{arg}(M_3), \text{arg}(A_{u0}), \text{arg}(A_{d0}), \text{arg}(A_{e0}) = 0 \text{ or } \pi, \quad (5.20)$$

then the only CP-violating phase in the theory will be the usual CKM phase found in the ordinary Yukawa couplings. Together, the conditions eqs. (5.18)-(5.20) make up a rather weak version of what is
often called the hypothesis of soft supersymmetry-breaking universality. The MSSM with these flavor- and CP-preserving relations imposed has far fewer parameters than the most general case. Besides the usual Standard Model gauge and Yukawa coupling parameters, there are 3 independent real gaugino masses, only 5 real squark and slepton squared mass parameters, 3 real scalar cubic coupling parameters, and 4 Higgs mass parameters (one of which can be traded for the known electroweak breaking scale).

It must be mentioned in passing that there are two other possible types of explanations for the suppression of flavor violation in the MSSM, which could replace the universality hypothesis of eqs. (5.18)-(5.20). One might refer to them as “irrelevancy” and “alignment” of the soft masses. The “irrelevancy” idea is that the sparticles masses are extremely heavy, so that their contributions to flavor-changing and CP-violating diagrams like Figures 5.7a,b are suppressed, as can be seen for example in eqs. (5.15)-(5.17). In practice, however, the degree of suppression needed typically requires $m_{\text{soft}}$ much larger than 1 TeV for at least some of the scalar masses; this seems to go directly against the motivation for supersymmetry as a cure for the hierarchy problem as discussed in the Introduction. Nevertheless, it has been argued that this is a sensible possibility [98, 99]. The “alignment” idea is that the squark squared-mass matrices do not have the flavor-blindness indicated in eq. (5.18), but are arranged in flavor space to be aligned with the relevant Yukawa matrices in just such a way as to avoid large flavor-changing effects [55, 100]. The alignment models typically require rather special flavor symmetries. In any case, we will not discuss these possibilities further.

The soft-breaking universality relations eqs. (5.18)-(5.20), or stronger (more special) versions of them, can be presumed to be the result of some specific model for the origin of supersymmetry breaking, although there is considerable disagreement among theorists as to what the specific model should actually be. In any case, they are indicative of an assumed underlying simplicity or symmetry of the Lagrangian at some very high energy scale $Q_0$. If we used this Lagrangian to compute masses and cross-sections and decay rates for experiments at ordinary energies near the electroweak scale, the results would involve large logarithms of order $\ln(Q_0/m_Z)$ coming from loop diagrams. As is usual in quantum field theory, the large logarithms can be conveniently resummed using renormalization group (RG) equations, by treating the couplings and masses appearing in the Lagrangian as running parameters. Therefore, eqs. (5.18)-(5.20) should be interpreted as boundary conditions on the running soft parameters at the scale $Q_0$, which is likely very far removed from direct experimental probes. We must then RG-evolve all of the soft parameters, the superpotential parameters, and the gauge couplings down to the electroweak scale or comparable scales where humans perform experiments.

At the electroweak scale, eqs. (5.18) and (5.19) will no longer hold, even if they were exactly true at the input scale $Q_0$. However, to a good approximation, key flavor- and CP-conserving properties remain. This is because, as we will see in section 5.5 below, RG corrections due to gauge interactions will respect the form of eqs. (5.18) and (5.19), while RG corrections due to Yukawa interactions are quite small except for couplings involving the top, bottom, and tau flavors. Therefore, the (scalar)$^3$ couplings and scalar squared-mass mixings should be quite negligible for the squarks and sleptons of the first two families. Furthermore, RG evolution does not introduce new CP-violating phases. Therefore, if universality can be arranged to hold at the input scale, supersymmetric contributions to flavor-changing and CP-violating observables can be acceptably small in comparison to present limits (although quite possibly measurable in future experiments).

One good reason to be optimistic that such a program can succeed is the celebrated apparent unification of gauge couplings in the MSSM [101]. The 1-loop RG equations for the Standard Model gauge couplings $g_1, g_2, g_3$ are

$$\beta_{g_a} \equiv \frac{d}{dt} g_a = \frac{1}{16\pi^2} b_a g_a^3,$$

$$(b_1, b_2, b_3) = \left\{ \begin{array}{ll}
(41/10, -19/6, -7) & \text{Standard Model} \\
(33/5, 1, -3) & \text{MSSM} 
\end{array} \right.$$ (5.21)

where $t = \ln(Q/Q_0)$, with $Q$ the RG scale. The MSSM coefficients are larger because of the extra
MSSM particles in loops. The normalization for $g_1$ here is chosen to agree with the canonical covariant derivative for grand unification of the gauge group $SU(3)_C \times SU(2)_L \times U(1)_Y$ into $SU(5)$ or $SO(10)$. Thus in terms of the conventional electroweak gauge couplings $g$ and $g'$ with $e = g \sin \theta_W = g' \cos \theta_W$, one has $g_2 = g$ and $g_1 = \sqrt{5/3} g'$. The quantities $\alpha_a = g_a^2/4\pi$ have the nice property that their reciprocals run linearly with RG scale at one-loop order:

$$\frac{d}{dt} \alpha_a^{-1} = -\frac{b_a}{2\pi} \quad (a = 1, 2, 3) \tag{5.22}$$

Figure 5.8 compares the RG evolution of the $\alpha_a^{-1}$, including two-loop effects, in the Standard Model (dashed lines) and the MSSM (solid lines). Unlike the Standard Model, the MSSM includes just the right particle content to ensure that the gauge couplings can unify, at a scale $M_U \sim 2 \times 10^{16}$ GeV. While the apparent unification of gauge couplings at $M_U$ might be just an accident, it may also be taken as a strong hint in favor of a grand unified theory (GUT) or superstring models, both of which can naturally accommodate gauge coupling unification below $M_P$. Furthermore, if this hint is taken seriously, then we can reasonably expect to be able to apply a similar RG analysis to the other MSSM couplings and soft masses as well. The next section discusses the form of the necessary RG equations.

5.5 Renormalization Group equations for the MSSM

In order to translate a set of predictions at an input scale into physically meaningful quantities that describe physics near the electroweak scale, it is necessary to evolve the gauge couplings, superpotential parameters, and soft terms using their renormalization group (RG) equations. This ensures that the loop expansions for calculations of observables will not suffer from very large logarithms.

As a technical aside, some care is required in choosing regularization and renormalization procedures in supersymmetry. The most popular regularization method for computations of radiative corrections within the Standard Model is dimensional regularization (DREG), in which the number of spacetime dimensions is continued to $d = 4 - 2\epsilon$. Unfortunately, DREG introduces a spurious violation of supersymmetry, because it has a mismatch between the numbers of gauge boson degrees of freedom and the gaugino degrees of freedom off-shell. This mismatch is only $2\epsilon$, but can be multiplied by factors up to $1/\epsilon^n$ in an $n$-loop calculation. In DREG, supersymmetric relations between dimensionless coupling constants (“supersymmetric Ward identities”) are therefore not explicitly respected by radiative...
corrections involving the finite parts of one-loop graphs and by the divergent parts of two-loop graphs. Instead, one may use the slightly different scheme known as regularization by dimensional reduction, or DRED, which does respect supersymmetry \[102\]. In the DRED method, all momentum integrals are still performed in \(d = 4 - 2\varepsilon\) dimensions, but the vector index \(\mu\) on the gauge boson fields \(A^a_{\mu}\) now runs over all 4 dimensions to maintain the match with the gaugino degrees of freedom. Running couplings are then renormalized using DRED with modified minimal subtraction (\(\overline{\text{DR}}\)) rather than the usual DREG with modified minimal subtraction (\(\overline{\text{MS}}\)). In particular, the boundary conditions at the input scale should presumably be applied in a supersymmetry-preserving scheme like \(\overline{\text{DR}}\). One loop \(\beta\)-functions are always the same in these two schemes, but it is important to realize that the \(\overline{\text{MS}}\) scheme does violate supersymmetry, so that \(\overline{\text{DR}}\) is preferred from that point of view. (The NSVZ scheme \[107\] also respects supersymmetry and has some very useful properties, but with a less obvious connection to calculations of physical observables. It is also possible, but not always very practical, to work consistently within the \(\overline{\text{MS}}\) scheme, as long as one translates all \(\overline{\text{DR}}\) couplings and masses into their \(\overline{\text{MS}}\) counterparts \[108\]-\[110\].)

A general and powerful result known as the supersymmetric non-renormalization theorem \[111\] governs the form of the renormalization group equations for supersymmetric theories. This theorem implies that the logarithmically divergent contributions to a particular process can always be written in terms of wave-function renormalizations, without any coupling vertex renormalization.‡ It can be proved most easily using superfield techniques. For the parameters appearing in the superpotential eq. (3.47), the implication is that

\[
\begin{align*}
\beta_{y^{ijk}} &\equiv \frac{d}{dt} y^{ijk} = \gamma^i_n y^{njk} + \gamma^j_n y^{ink} + \gamma^k_n y^{ijn}, \\
\beta_{M^{ij}} &\equiv \frac{d}{dt} M^{ij} = \gamma^i_n M^{nj} + \gamma^j_n M^{in}, \\
\beta_{L^i} &\equiv \frac{d}{dt} L^i = \gamma^i_n L^n,
\end{align*}
\]

(5.23) (5.24) (5.25)

where the \(\gamma^i_j\) are anomalous dimension matrices associated with the superfields, which generally have to be calculated in a perturbative loop expansion. [Recall \(t = \ln(Q/Q_0)\), where \(Q\) is the renormalization scale, and \(Q_0\) is a reference scale.] The anomalous dimensions and RG equations for softly broken supersymmetry are now known up to 3-loop order, with some partial 4-loop results; they have been given in refs. \[112\]-\[117\]. There are also relations, good to all orders in perturbation theory, that give the RG equations for soft supersymmetry couplings in terms of those for the supersymmetric couplings \[107\] \[118\]. Here we will only use the 1-loop approximation, for simplicity.

In general, at 1-loop order,

\[
\gamma^i_j = \frac{1}{16\pi^2} \left[ \frac{1}{2} y^{imn} y^{*}_{jmn} - 2 g^2_a C_a(i) \delta^i_j \right],
\]

(5.26)

where \(C_a(i)\) are the quadratic Casimir group theory invariants for the superfield \(\Phi_i\), defined in terms of the Lie algebra generators \(T^a\) by

\[
(T^a T^a)_i^j = C_a(i) \delta^i_j
\]

(5.27)

\[1\] Even the DRED scheme may not provide a supersymmetric regulator, because of either ambiguities or inconsistencies (depending on the precise method) appearing at five-loop order at the latest \[103\]. Fortunately, this does not seem to cause practical difficulties \[104\] \[105\]. See also ref. \[106\] for an interesting proposal that avoids doing violence to the number of spacetime dimensions.

\[2\] Actually, there is vertex renormalization working in a supersymmetric gauge theory in which auxiliary fields have been integrated out, but the sum of divergent contributions for a process always has the form of wave-function renormalization. This is related to the fact that the anomalous dimensions of the superfields differ, by gauge-fixing dependent terms, from the anomalous dimensions of the fermion and boson component fields \[31\].
with gauge couplings \(g_a\). Explicitly, for the MSSM supermultiplets:

\[
C_3(i) = \begin{cases} 
4/3 & \text{for } \Phi_i = Q, \overline{u}, \overline{d}, \\
0 & \text{for } \Phi_i = L, \overline{\tau}, H_u, H_d,
\end{cases} \quad (5.28)
\]

\[
C_2(i) = \begin{cases} 
3/4 & \text{for } \Phi_i = Q, L, H_u, H_d, \\
0 & \text{for } \Phi_i = \overline{\tau}, \overline{\tau},
\end{cases} \quad (5.29)
\]

\[
C_1(i) = 3Y_i^2/5 \text{ for each } \Phi_i \text{ with weak hypercharge } Y_i. \quad (5.30)
\]

For the one-loop renormalization of gauge couplings, one has in general

\[
\beta_{g_a} = \frac{d}{dt} g_a = \frac{1}{16\pi^2} g_a^2 \left[ \sum_i I_a(i) - 3C_a(G) \right], \quad (5.31)
\]

where \(C_a(G)\) is the quadratic Casimir invariant of the group \([0 \text{ for } U(1), \text{ and } N \text{ for } SU(N)\], and \(I_a(i)\) is the Dynkin index of the chiral supermultiplet \(\phi_i\) normalized to \(1/2\) for each fundamental representation of \(SU(N)\) and to \(3Y_i^2/5 \text{ for } U(1)_Y\). Equation (5.21) is a special case of this.

The 1-loop renormalization group equations for the general soft supersymmetry breaking Lagrangian parameters appearing in eq. (4.11) are:

\[
\beta_{M_a} \equiv \frac{d}{dt} M_a = \frac{1}{16\pi^2} g_a^2 \left[ \sum_n I_a(n) - 6C_a(G) \right] M_a, \quad (5.32)
\]

\[
\beta_{a^{ijk}} \equiv \frac{d}{dt} a^{ijk} = \frac{1}{16\pi^2} \left[ \frac{1}{2} a^{ijk} y_{pmn}^k y_{k^m}^n + y_{pmn}^* a^{mnp} + g_a^2 C_a(i)(4M_a y_{ij}^k - 2a^{ijk}) \right] + (i \leftrightarrow k) + (j \leftrightarrow k), \quad (5.33)
\]

\[
\beta_{b_{ij}} \equiv \frac{d}{dt} b_{ij} = \frac{1}{16\pi^2} \left[ \frac{1}{2} b_{ij} y_{pmn}^j y_{k^m}^n + y_{pmn}^* b_{mnp} + M_i^j y_{pmn}^* a^{mnp} \right] + (i \leftrightarrow j), \quad (5.34)
\]

\[
\beta_{(m^2)^i} \equiv \frac{d}{dt} (m^2)^i = \frac{1}{16\pi^2} \left[ \frac{1}{2} y_{pmn}^j y_{k^m}^n \rho^p + a_{mnp}^* \rho^p \right] + (i \leftrightarrow j), \quad (5.35)
\]

\[
\beta_{(m^2)_i} = \frac{d}{dt} (m^2)_i = \frac{1}{16\pi^2} \left[ \frac{1}{2} y_{pmn}^j y_{k^m}^n (m^2)^j_n + 2y_{pmn}^* y_{k^m}^n (m^2)^n_j + 2y_{pmn}^* y_{k^m}^n (m^2)^n_j \right] + a_{ipq}^* y_{ipq} - 8g_a^2 C_a(i) |M_a|^2 \delta_i^j + 2g_a^2 (T^a)^i_j \text{Tr}(T^a m^2). \quad (5.36)
\]

Applying the above results to the special case of the MSSM, we will use the approximation that only the third-family Yukawa couplings are significant, as in eq. (5.2). Then the Higgs and third-family superfield anomalous dimensions are diagonal matrices, and from eq. (5.20) they are, at 1-loop order:

\[
\gamma_{H_u} = \frac{1}{16\pi^2} \left[ 3y_t^* y_t - \frac{3}{2} g_2 - \frac{3}{10} g_1^2 \right], \quad (5.37)
\]

\[
\gamma_{H_d} = \frac{1}{16\pi^2} \left[ 3y_t^* y_t + y_r^* y_r - \frac{3}{2} g_2 - \frac{3}{10} g_1^2 \right], \quad (5.38)
\]

\[
\gamma_{Q_3} = \frac{1}{16\pi^2} \left[ y_t^* y_t + y_b^* y_b - \frac{8}{3} g_3^2 - \frac{3}{2} g_2 - \frac{1}{30} g_1^2 \right], \quad (5.39)
\]

\[
\gamma_{\overline{\tau}_3} = \frac{1}{16\pi^2} \left[ 2y_t^* y_t - \frac{8}{3} g_3 - \frac{8}{15} g_1^2 \right], \quad (5.40)
\]

\[
\gamma_{\overline{\tau}_3} = \frac{1}{16\pi^2} \left[ 2y_t^* y_t - \frac{8}{3} g_3 - \frac{2}{15} g_1^2 \right], \quad (5.41)
\]
\[ \gamma_{L_3} = \frac{1}{16\pi^2} \left[ y_r^* y_r - \frac{3}{2} g_2^2 - \frac{3}{10} g_1^2 \right], \]
\[ \gamma_{\tau_3} = \frac{1}{16\pi^2} \left[ -y_r^* y_r - \frac{6}{5} g_1^2 \right]. \]

The one-loop RG equations for the gauge couplings \(g_1, g_2, \) and \(g_3\) were already listed in eq. \(5.21\). The presence of soft supersymmetry breaking does not affect eqs. \(5.21\) and \((5.44)\)–\((5.47)\). As a result of the supersymmetric non-renormalization theorem, the \(\beta\)-functions for each supersymmetric parameter are proportional to the parameter itself. One consequence of this is that once we have a theory that can explain why \(\mu\) is of order \(10^2\) or \(10^3\) GeV at tree-level, we do not have to worry about \(\mu\) being made very large by radiative corrections involving the masses of some very heavy unknown particles; all such RG corrections to \(\mu\) will be directly proportional to \(\mu\) itself and to some combinations of dimensionless couplings.

The one-loop RG equations for the three gaugino mass parameters in the MSSM are determined by the same quantities \(t_a^{\text{MSSM}}\) that appear in the gauge coupling RG eqs. \((5.21)\):

\[ \beta_{M_a} \equiv \frac{d}{dt} M_a = \frac{1}{8\pi^2} b_a g_3^2 M_a \quad (b_a = 33/5, 1, -3) \]

for \(a = 1, 2, 3\). It follows that the three ratios \(M_a/g_3^2\) are each constant (RG scale independent) up to small two-loop corrections. Since the gauge couplings are observed to unify at \(Q = M_U = 2 \times 10^{16}\) GeV, it is a popular assumption that the gaugino masses also unify\(^1\) near that scale, with a value called \(m_{1/2}\). If so, then it follows that

\[ \frac{M_1}{g_1^2} = \frac{M_2}{g_2^2} = \frac{M_3}{g_3^2} = \frac{m_{1/2}}{g_U^2} \]

at any RG scale, up to small (and known) two-loop effects and possibly much larger (and not so known) threshold effects near \(M_U\). Here \(g_U\) is the unified gauge coupling at \(Q = M_U\). The hypothesis of eq. \((5.49)\) is particularly powerful because the gaugino mass parameters feed strongly into the RG equations for all of the other soft terms, as we are about to see.

Next we consider the 1-loop RG equations for the analytic soft parameters \(a_u, a_d, a_e\). In models obeying eq. \((5.19)\), these matrices start off proportional to the corresponding Yukawa couplings at the input scale. The RG evolution respects this property. With the approximation of eq. \((5.2)\), one can therefore also write, at any RG scale,

\[ a_u \approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & a_t \end{pmatrix}, \quad a_d \approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & a_b \end{pmatrix}, \quad a_e \approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & a_r \end{pmatrix}, \]

\(^1\)In GUT models, it is automatic that the gauge couplings and gaugino masses are unified at all scales \(Q \geq M_U\), because in the unified theory the gauginos all live in the same representation of the unified gauge group. In many superstring models, this can also be a good approximation.
which defines\(^\dagger\) running parameters \(a_t, a_b, \) and \(a_\tau\). In this approximation, the RG equations for these parameters and \(b\) are

\[
16\pi^2 \frac{d}{dt} a_t = a_t \left[ 18y_t^* y_t + y_b^* y_b - \frac{16}{3} g_3^2 - 3g_2^2 - \frac{13}{15} g_1^2 \right] + 2a_b y_b^* y_t \\
+ y_b \left[ \frac{32}{3} g_3^2 M_3 + 6g_2^2 M_2 + \frac{26}{15} g_1^2 M_1 \right],
\]

(5.51)

\[
16\pi^2 \frac{d}{dt} a_b = a_b \left[ 18y_b^* y_b + y_t^* y_t + y_\tau^* y_\tau - \frac{16}{3} g_3^2 - 3g_2^2 - \frac{7}{15} g_1^2 \right] + 2a_t y_b^* y_t + 2a_\tau y_\tau^* y_b \\
+ y_b \left[ \frac{32}{3} g_3^2 M_3 + 6g_2^2 M_2 + \frac{14}{15} g_1^2 M_1 \right],
\]

(5.52)

\[
16\pi^2 \frac{d}{dt} a_\tau = a_\tau \left[ 12y_\tau^* y_\tau + 3y_b^* y_b - 3g_2^2 - \frac{9}{5} g_1^2 \right] + 6a_b y_b^* y_\tau + y_\tau \left[ 6g_2^2 M_2 + \frac{18}{5} g_1^2 M_1 \right],
\]

(5.53)

\[
16\pi^2 \frac{d}{dt} b = b \left[ 3y_b^* y_t + y_b^* y_b + y_\tau^* y_\tau - 3g_2^2 - \frac{3}{5} g_1^2 \right] \\
+ \mu \left[ 6a_t y_t^* + 6a_b y_b^* + 2a_\tau y_\tau^* + 6g_2^2 M_2 + \frac{6}{5} g_1^2 M_1 \right]. 
\]

(5.54)

The \(\beta\)-function for each of these soft parameters is not proportional to the parameter itself, because couplings that violate supersymmetry are not protected by the supersymmetric non-renormalization theorem. So, even if \(a_t, a_b, a_\tau\) and \(b\) vanish at the input scale, the RG corrections proportional to gaugino masses appearing in eqs. (5.51) - (5.54) ensure that they will not vanish at the electroweak scale.

Next let us consider the RG equations for the scalar squared masses in the MSSM. In the approximation of eqs. (5.2) and (5.3), the squarks and sleptons of the first two families have only gauge interactions. This means that if the scalar squared masses satisfy a boundary condition like eq. (5.18) at an input RG scale, then when renormalized to any other RG scale, they will still be almost diagonal, with the approximate form

\[
m^2_\tilde{Q} \approx \begin{pmatrix} m^2_{\tilde{Q}_1} & 0 & 0 \\ 0 & m^2_{\tilde{Q}_1} & 0 \\ 0 & 0 & m^2_{\tilde{Q}_2} \end{pmatrix}, \quad m^2_\tilde{\tau} \approx \begin{pmatrix} m^2_{\tilde{\tau}_1} & 0 & 0 \\ 0 & m^2_{\tilde{\tau}_1} & 0 \\ 0 & 0 & m^2_{\tilde{\tau}_3} \end{pmatrix}, 
\]

(5.55)

etc. The first and second family squarks and sleptons with given gauge quantum numbers remain very nearly degenerate, but the third-family squarks and sleptons feel the effects of the larger Yukawa couplings and so their squared masses get renormalized differently. The one-loop RG equations for the first and second family squark and slepton squared masses are

\[
16\pi^2 \frac{d}{dt} m^2_{\phi_i} = - \sum_{a=1,2,3} 8C_a(i) g_a^2 |M_a|^2 + \frac{6}{5} Y_i g_1^2 S 
\]

(5.56)

for each scalar \(\phi_i\), where the \(\sum_a\) is over the three gauge groups \(U(1)_Y, SU(2)_L\) and \(SU(3)_C\), with Casimir invariants \(C_a(i)\) as in eqs. (5.25) - (5.30), and \(M_a\) are the corresponding running gaugino mass parameters. Also,

\[
S \equiv \text{Tr}[Y_j m^2_{\phi_j}] = m^2_{H_u} - m^2_{H_d} + \text{Tr}[m^2_Q - m^2_{\tilde{\tau}} - 2m^2_{\tilde{\tau}} + m^2_3 + m^2_2]. 
\]

(5.57)

An important feature of eq. (5.56) is that the terms on the right-hand sides proportional to gaugino squared masses are negative, so\(^\dagger\) the scalar squared-mass parameters grow as they are RG-evolved from

\(^\dagger\) Rescaled soft parameters \(A_t = a_t/y_t, A_b = a_b/y_b, \) and \(A_\tau = a_\tau/y_\tau\) are commonly used in the literature. We do not follow this notation, because it cannot be generalized beyond the approximation of eqs. (5.21) - (5.30), without introducing horrible complications such as non-polynomial RG equations, and because \(a_t, a_b, \) and \(a_\tau\) are the couplings that actually appear in the Lagrangian anyway.

\(^\dagger\) The contributions proportional to \(S\) are relatively small in most known realistic models.
the input scale down to the electroweak scale. Even if the scalars have zero or very small masses at the input scale, they can obtain large positive squared masses at the electroweak scale, thanks to the effects of the gaugino masses.

The RG equations for the squared-mass parameters of the Higgs scalars and third-family squarks and sleptons get the same gauge contributions as in eq. (5.56), but they also have contributions due to the large Yukawa \((y_t,b,\tau)\) and soft \((a_t,b,\tau)\) couplings. At one-loop order, these only appear in three combinations:

\[
X_t = 2|y_t|^2(m_{H_u}^2 + m_{Q_3}^2 + m_{\tilde{d}_3}^2) + 2|a_t|^2,
\]

\[
X_b = 2|y_b|^2(m_{H_u}^2 + m_{Q_3}^2 + m_{\tilde{d}_3}^2) + 2|a_b|^2,
\]

\[
X_\tau = 2|y_\tau|^2(m_{H_d}^2 + m_{L_3}^2 + m_{\tilde{e}_3}^2) + 2|a_\tau|^2.
\]

In terms of these quantities, the RG equations for the soft Higgs squared-mass parameters \(m_{H_u}^2\) and \(m_{H_d}^2\) are

\[
16\pi^2 \frac{d}{dt} m_{H_u}^2 = 3X_t - 6g_2^2|M_2|^2 - \frac{6}{5}g_1^2|M_1|^2 + \frac{3}{5}g_1^2S,
\]

\[
16\pi^2 \frac{d}{dt} m_{H_d}^2 = 3X_b + X_\tau - 6g_2^2|M_2|^2 - \frac{6}{5}g_1^2|M_1|^2 - \frac{3}{5}g_1^2S.
\]

Note that \(X_t, X_b,\) and \(X_\tau\) are generally positive, so their effect is to decrease the Higgs masses as one evolves the RG equations down from the input scale to the electroweak scale. If \(y_t\) is the largest of the Yukawa couplings, as suggested by the experimental fact that the top quark is heavy, then \(X_t\) will typically be much larger than \(X_b\) and \(X_\tau\). This can cause the RG-evolved \(m_{H_u}^2\) to run negative near the electroweak scale, helping to destabilize the point \(H_u = H_d = 0\) and so provoking a Higgs VEV (for a linear combination of \(H_u\) and \(H_d\), as we will see in section 7.1), which is just what we want.\(^1\) Thus a large top Yukawa coupling favors the breakdown of the electroweak symmetry breaking because it induces negative radiative corrections to the Higgs squared mass.

The third-family squark and slepton squared-mass parameters also get contributions that depend on \(X_t, X_b,\) and \(X_\tau\). Their RG equations are given by

\[
16\pi^2 \frac{d}{dt} m_{Q_3}^2 = X_t + X_b - \frac{32}{3}g_3^2|M_3|^2 - 6g_2^2|M_2|^2 - \frac{2}{15}g_2^2|M_1|^2 + \frac{1}{5}g_1^2S,
\]

\[
16\pi^2 \frac{d}{dt} m_{\tilde{d}_3}^2 = 2X_t - \frac{32}{3}g_3^2|M_3|^2 - \frac{32}{15}g_2^2|M_1|^2 - \frac{4}{5}g_1^2S,
\]

\[
16\pi^2 \frac{d}{dt} m_{L_3}^2 = 2X_b - \frac{32}{3}g_3^2|M_3|^2 - \frac{8}{15}g_2^2|M_1|^2 + \frac{2}{5}g_1^2S,
\]

\[
16\pi^2 \frac{d}{dt} m_{\tilde{e}_3}^2 = X_\tau - 6g_2^2|M_2|^2 - \frac{6}{5}g_1^2|M_1|^2 - \frac{3}{5}g_1^2S,
\]

\[
16\pi^2 \frac{d}{dt} m_{\tilde{e}_3}^2 = 2X_\tau - \frac{24}{5}g_1^2|M_1|^2 + \frac{6}{5}g_1^2S.
\]

In eqs. (5.61)-(5.67), the terms proportional to \(|M_3|^2, |M_2|^2, |M_1|^2,\) and \(S\) are just the same ones as in eq. (5.56). Note that the terms proportional to \(X_t\) and \(X_b\) appear with smaller numerical coefficients in the \(m_{Q_3}^2, m_{\tilde{d}_3}^2, m_{L_3}^2\) RG equations than they did for the Higgs scalars, and they do not appear at all in the \(m_{\tilde{e}_3}^2\) RG equations. Furthermore, the third-family squark squared masses get a large positive contribution proportional to \(|M_3|^2\) from the RG evolution, which the Higgs scalars do not get.

---

\(^1\) One should think of \(m_{H_u}^2\) as a parameter unto itself, and not as the square of some mythical real number \(m_{H_u}\). So there is nothing strange about having \(m_{H_u}^2 < 0\). However, strictly speaking \(m_{H_u}^2 < 0\) is neither necessary nor sufficient for electroweak symmetry breaking; see section 7.1.
These facts make it plausible that the Higgs scalars in the MSSM get VEVs, while the squarks and sleptons, having large positive squared mass, do not.

An examination of the RG equations (5.51)-(5.54), (5.56), and (5.61)-(5.67) reveals that if the gaugino mass parameters $M_1$, $M_2$, and $M_3$ are non-zero at the input scale, then all of the other soft terms will be generated too. This implies that models in which gaugino masses dominate over all other effects in the soft supersymmetry breaking Lagrangian at the input scale can be viable. On the other hand, if the gaugino masses were to vanish at tree-level, then they would not get any contributions to their masses at one-loop order; in that case the gauginos would be extremely light and the model would not be phenomenologically acceptable.

Viable models for the origin of supersymmetry breaking typically make predictions for the MSSM soft terms that are refinements of eqs. (5.18)-(5.20). These predictions can then be used as boundary conditions for the RG equations listed above. In the next section we will study the ideas that go into making such predictions, before turning to their implications for the MSSM spectrum in section 7.

6 Origins of supersymmetry breaking

6.1 General considerations for spontaneous supersymmetry breaking

In the MSSM, supersymmetry breaking is simply introduced explicitly. However, we have seen that the soft parameters cannot be arbitrary. In order to understand how patterns like eqs. (5.18), (5.19) and (5.20) can emerge, it is necessary to consider models in which supersymmetry is spontaneously broken. By definition, this means that the vacuum state $|0\rangle$ is not invariant under supersymmetry transformations, so $Q_\alpha|0\rangle \neq 0$ and $Q_\alpha^\dagger|0\rangle \neq 0$. Now, in global supersymmetry, the Hamiltonian operator $H$ is related to the supersymmetry generators through the algebra eq. (3.30):

$$H = P^0 = \frac{1}{4} (Q_1 Q_1^\dagger + Q_1^\dagger Q_1 + Q_2 Q_2^\dagger + Q_2^\dagger Q_2).$$

If supersymmetry is unbroken in the vacuum state, it follows that $H|0\rangle = 0$ and the vacuum has zero energy. Conversely, if supersymmetry is spontaneously broken in the vacuum state, then the vacuum must have positive energy, since

$$\langle 0|H|0\rangle = \frac{1}{4} \left( \|Q_1^\dagger|0\rangle\|^2 + \|Q_1|0\rangle\|^2 + \|Q_2^\dagger|0\rangle\|^2 + \|Q_2|0\rangle\|^2 \right) > 0$$

if the Hilbert space is to have positive norm. If spacetime-dependent effects and fermion condensates can be neglected, then $\langle 0|H|0\rangle = \langle 0|V|0\rangle$, where $V$ is the scalar potential in eq. (3.75). Therefore, supersymmetry will be spontaneously broken if $F_i$ and/or $D^a$ does not vanish in the ground state. If any state exists in which all $F_i$ and $D^a$ vanish, then it will have zero energy, implying that supersymmetry cannot be spontaneously broken in the true ground state. So, the way to achieve spontaneous supersymmetry breaking is to look for models in which the equations $F_i = 0$ and $D^a = 0$ cannot be simultaneously satisfied for any values of the fields.

The spontaneous breaking of a global symmetry always implies a massless Nambu-Goldstone mode with the same quantum numbers as the broken symmetry generator. In the case of global supersymmetry, the broken generator is the fermionic charge $Q_\alpha$, so the Nambu-Goldstone particle ought to be a massless neutral Weyl fermion, called the goldstino. To prove it, consider a general supersymmetric model with both gauge and chiral supermultiplets as in section 3. The fermionic degrees of freedom consist of gauginos ($\lambda^a$) and chiral fermions ($\psi_i$). After some of the scalar fields in the theory obtain VEVs, the fermion mass matrix has the form:

$$m_F = \begin{pmatrix} 0 & \sqrt{2}g_b \langle (\phi^*)^a T^b \rangle^j \\ \sqrt{2}g_a \langle (\phi^*) T^a \rangle^j & \langle W^j \rangle \end{pmatrix}$$

(6.3)
in the \((\lambda^a, \psi_i)\) basis. [The off-diagonal entries in this matrix come from the first term in the second line of eq. \ref{eq:5.22}, and the lower right entry can be seen in eq. \ref{eq:5.29}]. Now observe that \(\mathbf{m}_F\) annihilates the vector
\[
\tilde{G} = \left( \frac{\langle D^a \rangle}{\sqrt{2}} \right).
\] (6.4)

The first row of \(\mathbf{m}_F\) annihilates \(\tilde{G}\) by virtue of the requirement eq. \ref{eq:5.31} that the superpotential is gauge invariant, and the second row does so because of the condition \((\partial V/\partial \phi_i) = 0\), which must be satisfied at a minimum of the scalar potential. Equation (6.4) is therefore proportional to the goldstino wavefunction; it is non-trivial if and only if at least one of the auxiliary fields has a VEV, breaking supersymmetry. So we have proved that if global supersymmetry is spontaneously broken, then there must be a massless goldstino, and that its components among the various fermions in the theory are just proportional to the corresponding auxiliary field VEVs.

There is also a useful sum rule that governs the tree-level squared masses of particles in theories with spontaneously broken supersymmetry. For a general theory of the type discussed in section 3, the squared masses of the real scalar degrees of freedom are the eigenvalues of the matrix
\[
\mathbf{m}_S^2 = \begin{pmatrix}
W_{jk}W^{ik} + g_a^2[(T^a \phi)_j(T^a \phi)] + T^a_{ji}D^a
& W_{jk}W^k + g_a^2(T^a \phi)_i(T^a \phi)_j \\
W^{ijk}W^k + g_a^2(\phi^i T^a j) + T^a_{ji}D^a
& W^{ik}W^j + g_a^2[(T^a \phi)_i(T^a \phi)_j + T^a_{ij}D^a]
\end{pmatrix},
\] (6.5)
since the quadratic part of the tree-level potential is
\[
V = (\phi^i \phi_j) \mathbf{m}_S^2 (\phi_i \phi_j).
\] (6.6)

Here \(W^{ijk} = \delta^3W/\delta \phi_i \delta \phi_j \delta \phi_k\), and the scalar fields on the right-hand side of eq. \ref{eq:5.5} are understood to be replaced by their VEVs. It follows that the sum of the real scalar squared-mass eigenvalues is
\[
\text{Tr}(\mathbf{m}_S^2) = 2W_{ik}W^{ik} + 2g_a^2[C_a(i)\phi^i \phi_i + \text{Tr}(T^a)D^a],
\] (6.7)
with the Casimir invariants \(C_a(i)\) defined by eq. \ref{eq:5.22}. Meanwhile, the squared masses of the two-component fermions are given by the eigenvalues of
\[
\mathbf{m}_F^\dagger \mathbf{m}_F = \begin{pmatrix}
2g_a g_b(\phi^i T^a b \phi)_k W^{ik}
& \sqrt{2}g_a(T^a \phi)_j W^{ik} \\
\sqrt{2}g_a(T^a \phi)_k W^{ik}
& W^{kj}W_{jk} + 2g_a^2(T^a \phi)_j(\phi^i T^a i) + T^a_{ij}D^a
\end{pmatrix},
\] (6.8)
so the sum of the two-component fermion squared masses is
\[
\text{Tr}(\mathbf{m}_F^\dagger \mathbf{m}_F) = W^{ik}W_{ik} + 4g_a^2C_a(i)\phi^i \phi_i.
\] (6.9)

Finally, the vector squared masses are:
\[
\mathbf{m}_V^2 = g_a^2(\phi^i \{ T^a, T^b \} \phi),
\] (6.10)
so
\[
\text{Tr}(\mathbf{m}_V^2) = 2g_a^2C_a(i)\phi^i \phi_i.
\] (6.11)

It follows that the supertrace of the tree-level squared-mass eigenvalues, defined in general by a weighted sum over all particles with spin \(j\):
\[
\text{STr}(m^2) = \sum_j (-1)^j(2j + 1)\text{Tr}(m_j^2),
\] (6.12)
satisfies the sum rule
\[
\text{STr}(m^2) = \text{Tr}(\mathbf{m}_S^2) - 2\text{Tr}(\mathbf{m}_F^\dagger \mathbf{m}_F) + 3\text{Tr}(\mathbf{m}_V^2) = 2g_a^2\text{Tr}(T^a)D^a = 0.
\] (6.13)
The last equality assumes that the traces of the \(U(1)_Y\) charges over the chiral superfields are 0. This holds for \(U(1)_Y\) in the MSSM, and more generally for any non-anomalous gauge symmetry. The sum rule eq. (6.13) is often a useful check on models of spontaneous supersymmetry breaking.
6.2 Fayet-Iliopoulos (D-term) supersymmetry breaking

Supersymmetry breaking with a non-zero D-term VEV can occur through the Fayet-Iliopoulos mechanism \[119\]. If the gauge symmetry includes a U(1) factor, then one can introduce a term linear in the corresponding auxiliary field of the gauge supermultiplet:

\[
\mathcal{L}_{\text{Fayet–Iliopoulos}} = -\kappa D
\]

(6.14)

where \(\kappa\) is a constant with dimensions of [mass\(^2\)]. This term is gauge-invariant and supersymmetric by itself. [Note that for a U(1) gauge symmetry, the supersymmetry transformation \(\delta D\) in eq. (3.62) is a total derivative.] If we include it in the Lagrangian, then \(D\) may be forced to get a non-zero VEV. To see this, consider the relevant part of the scalar potential from eqs. (3.57) and (3.72):

\[
V = \kappa D - \frac{1}{2} D^2 - gD \sum_i q_i |\phi_i|^2.
\]

(6.15)

Here the \(q_i\) are the charges of the scalar fields \(\phi_i\) under the U(1) gauge group in question. The presence of the Fayet-Iliopoulos term modifies the equation of motion eq. (3.74) to

\[
D = \kappa - g \sum_i q_i |\phi_i|^2.
\]

(6.16)

Now suppose that the scalar fields \(\phi_i\) that are charged under the U(1) all have non-zero superpotential masses \(m_i\). (Gauge invariance then requires that they come in pairs with opposite charges.) Then the potential will have the form

\[
V = \sum_i |m_i|^2 |\phi_i|^2 + \frac{1}{2} (\kappa - g \sum_i q_i |\phi_i|^2)^2.
\]

(6.17)

Since this cannot vanish, supersymmetry must be broken; one can check that the minimum always occurs for non-zero \(D\). For the simplest case in which \(|m_i|^2 > gq_i\kappa\) for each \(i\), the minimum is realized for all \(\phi_i = 0\) and \(D = \kappa\), with the U(1) gauge symmetry unbroken. As further evidence that supersymmetry has indeed been spontaneously broken, note that the scalars then have squared masses \(|m_i|^2 - gq_i\kappa\), while their fermion partners have squared masses \(|m_i|^2\). The gaugino remains massless, as can be understood from the fact that it is the goldstino, as argued on general grounds in section 6.1.

For non-Abelian gauge groups, the analog of eq. (6.14) would not be gauge-invariant and is therefore not allowed, so only U(1) D-terms can drive spontaneous symmetry breaking. In the MSSM, one might imagine that the \(D\) term for U(1)\(_Y\) has a Fayet-Iliopoulos term as the principal source of supersymmetry breaking. Unfortunately, this cannot work, because the squarks and sleptons do not have superpotential mass terms. So, at least some of them would just get non-zero VEVs in order to make eq. (6.16) vanish. That would break color and/or electromagnetism, but not supersymmetry. Therefore, a Fayet-Iliopoulos term for U(1)\(_Y\) must be subdominant compared to other sources of supersymmetry breaking in the MSSM, if not absent altogether. One could instead attempt to trigger supersymmetry breaking with a Fayet-Iliopoulos term for some other U(1) gauge symmetry, which is as yet unknown because it is spontaneously broken at a very high mass scale or because it does not couple to the Standard Model particles. However, if this is the dominant source for supersymmetry breaking, it proves difficult to give appropriate masses to all of the MSSM particles, especially the gauginos. In any case, we will not discuss D-term breaking as the ultimate origin of supersymmetry violation any further (although it may not be ruled out \[120\]).

6.3 O’Raifeartaigh (F-term) supersymmetry breaking

Models where spontaneous supersymmetry breaking is ultimately due to a non-zero F-term VEV, called O’Raifeartaigh models \[121\], have brighter phenomenological prospects. The idea is to pick a
set of chiral supermultiplets \( \Phi_i \supset (\phi_i, \psi_i, F_i) \) and a superpotential \( W \) in such a way that the equations \( F_i = -\delta W^*/\delta \phi_i^{*} = 0 \) have no simultaneous solution. Then \( V = \sum_i |F_i|^2 \) will have to be positive at its minimum, ensuring that supersymmetry is broken.

The simplest example that does this has three chiral supermultiplets with

\[
W = -k \Phi_1 + m \Phi_2 \Phi_3 + \frac{y}{2} \Phi_1 \Phi_3^2. \tag{6.18}
\]

Note that \( W \) contains a linear term, with \( k \) having dimensions of \([\text{mass}]^2\). Such a term is allowed if the corresponding chiral supermultiplet is a gauge singlet. In fact, a linear term is necessary to achieve \( F \)-term breaking at tree-level in renormalizable theories, since otherwise setting all \( \phi_i = 0 \) will always give a supersymmetric global minimum with all \( F_i = 0 \). Without loss of generality, we can choose \( k, m, \) and \( y \) to be real and positive (by a phase rotation of the fields). The scalar potential following from eq. (6.18) is

\[
V = |F_1|^2 + |F_2|^2 + |F_3|^2, \tag{6.19}
\]

\[
F_1 = k - \frac{y}{2} \phi_3^2, \quad F_2 = -m \phi_3^*, \quad F_3 = -m \phi_2^* - y \phi_1^* \phi_3^*. \tag{6.20}
\]

Clearly, \( F_1 = 0 \) and \( F_2 = 0 \) are not compatible, so supersymmetry must indeed be broken. If \( m^2 > yk \) (which we assume from now on), then the absolute minimum of the potential is at \( \phi_2 = \phi_3 = 0 \) with \( \phi_1 \) undetermined, so \( F_1 = k \) and \( V = k^2 \) at the minimum. The fact that \( \phi_1 \) is undetermined is an example of a “flat direction” in the scalar potential; this is a common feature of supersymmetric models.\footnote{Non-polynomial superpotential terms, for example arising from non-perturbative effects, can avoid this requirement.}

If we presciently choose to expand \( V \) around \( \phi_1 = 0 \), the mass spectrum of the theory consists of 6 real scalars with tree-level squared masses

\[
0, \quad 0, \quad m_2^2, \quad m_2^2, \quad m^2 - yk, \quad m^2 + yk. \tag{6.21}
\]

Meanwhile, there are 3 Weyl fermions with squared masses

\[
0, \quad m^2, \quad m^2. \tag{6.22}
\]

The non-degeneracy of scalars and fermions is a clear sign that supersymmetry has been spontaneously broken. \[\text{Note that the sum rule eq. (6.13) is indeed satisfied by these squared masses.}\] The 0 eigenvalues in eqs. (6.21) and (6.22) correspond to the complex scalar \( \phi_1 \) and its fermionic partner \( \psi_1 \). However, \( \phi_1 \) and \( \psi_1 \) have different reasons for being massless. The masslessness of \( \phi_1 \) corresponds to the existence of the flat direction, since any value of \( \phi_1 \) gives the same energy at tree-level. This flat direction is an accidental feature of the classical scalar potential, and in this case it is removed (“lifted”) by quantum corrections. This can be seen by computing the Coleman-Weinberg one-loop effective potential \[\text{[123].}\]

A little calculation reveals that the global minimum is indeed fixed at \( \phi_1 = \phi_2 = \phi_3 = 0 \), with the complex scalar \( \phi_1 \) receiving a small positive-definite squared mass equal to

\[
m_{\phi_1}^2 = \frac{1}{16 \pi^2} y^2 m^2 \left[ \ln(1 - r^2) - 1 + \frac{1}{2} (r + 1/r) \ln \left( \frac{1 + r}{1 - r} \right) \right], \tag{6.23}
\]

where \( r = yk/m^2 \). \[\text{Equation (6.23) reduces to } m_{\phi_1}^2 = y^4 k^2/48 \pi^2 m^2 \text{ in the limit } yk \ll m^2.\] In contrast, the Weyl fermion \( \psi_1 \) remains exactly massless, because it is the goldstino, as predicted in section (6.1).

The O’Raifeartaigh superpotential determines the mass scale of supersymmetry breaking \( \sqrt{F_1} \) in terms of a dimensionful parameter \( k \) put in by hand. This appears somewhat artificial, since \( k \) will...
have to be tiny compared to $M_P^2$ in order to give the right order of magnitude for the MSSM soft terms. We would like to have a mechanism that can instead generate such scales naturally. This can be done in models of dynamical supersymmetry breaking, in which the small (compared to $M_P$) mass scales associated with supersymmetry breaking arise by dimensional transmutation. In other words, they generally feature a new asymptotically free non-Abelian gauge symmetry with a gauge coupling $g$ that is perturbative at $M_P$ and gets strong in the infrared at some smaller scale $\Lambda \sim e^{-\frac{8\pi^2}{|b|g_0^2}M_P}$, where $g_0$ is the running gauge coupling at $M_P$ with negative beta function $-|b|g^3/16\pi^2$. Just as in QCD, it is perfectly natural for $\Lambda$ to be many orders of magnitude below the Planck scale. Supersymmetry breaking may then be best described in terms of the effective dynamics of the strongly coupled theory. One possibility is that the auxiliary $F$ field for a composite chiral supermultiplet (built out of the fundamental fields, which transform under the new strongly coupled gauge group) obtains a VEV. Constructing non-perturbative models that actually break supersymmetry in an acceptable way is a non-trivial business; for more information see ref. [124]. For our purposes below, we can simply assume that an $F$-term has obtained a VEV.

6.4 The need for a separate supersymmetry-breaking sector

It is now clear that spontaneous supersymmetry breaking (dynamical or not) requires us to extend the MSSM. The ultimate supersymmetry-breaking order parameter cannot belong to any of the MSSM supermultiplets; a $D$-term VEV for $U(1)_Y$ does not lead to an acceptable spectrum, and there is no candidate gauge singlet whose $F$-term could develop a VEV. Therefore one must ask what effects are responsible for spontaneous supersymmetry breaking, and how supersymmetry breakdown is “communicated” to the MSSM particles. It is very difficult to achieve the latter in a phenomenologically viable way working only with renormalizable interactions at tree-level, even if the model is extended to involve new supermultiplets including gauge singlets. First, on general grounds it would be problematic to give masses to the MSSM gauginos, because the results of section 3 inform us that renormalizable supersymmetry never has any (scalar)-(gaugino)-(gaugino) couplings that could turn into gaugino mass terms when the scalar gets a VEV. Second, at least some of the MSSM squarks and sleptons would have to be unacceptably light, and should have been discovered already. This can be understood from the existence of sum rules that can be obtained in the same way as eq. (6.13) when the restrictions imposed by flavor symmetries are taken into account. For example, in the limit in which lepton flavors are conserved, the selectron mass eigenstates $\tilde{e}_1$ and $\tilde{e}_2$ could in general be mixtures of $\tilde{e}_L$ and $\tilde{e}_R$. But if they do not mix with other scalars, then part of the sum rule decouples from the rest, and one obtains:

$$m_{\tilde{e}_1}^2 + m_{\tilde{e}_2}^2 = 2m_{\tilde{e}}^2,$$  (6.24)

which is of course ruled out by experiment. Similar sum rules follow for each of the fermions of the Standard Model, at tree-level and in the limits in which the corresponding flavors are conserved. In principle, the sum rules can be evaded by introducing flavor-violating mixings, but it is very difficult to see how to make a viable model in this way. Even ignoring these problems, there is no obvious reason why the resulting MSSM soft supersymmetry-breaking terms in this type of model should satisfy flavor-blindness conditions like eqs. (5.18) or (5.19).

For these reasons, we expect that the MSSM soft terms arise indirectly or radiatively, rather than from tree-level renormalizable couplings to the supersymmetry-breaking order parameters. Supersymmetry breaking evidently occurs in a “hidden sector” of particles that have no (or only very small) direct couplings to the “visible sector” chiral supermultiplets of the MSSM. However, the two sectors do share some interactions that are responsible for mediating supersymmetry breaking from the hidden sector to the visible sector, resulting in the MSSM soft terms. (See Figure 6.1.) In this scenario, the tree-level squared mass sum rules need not hold, even approximately, for the physical masses of the
Figure 6.1: The presumed schematic structure for supersymmetry breaking.

visible sector fields, so that a phenomenologically viable superpartner mass spectrum is, in principle, achievable. As a bonus, if the mediating interactions are flavor-blind, then the soft terms appearing in the MSSM will automatically obey conditions like eqs. (5.18), (5.19) and (5.20).

There have been two main competing proposals for what the mediating interactions might be. The first (and historically the more popular) is that they are gravitational. More precisely, they are associated with the new physics, including gravity, that enters near the Planck scale. In this “gravity-mediated”, or Planck-scale-mediated supersymmetry breaking (PMSB) scenario, if supersymmetry is broken in the hidden sector by a VEV \( \langle F \rangle \), then the soft terms in the visible sector should be roughly

\[
m_{\text{soft}} \sim \langle F \rangle / M_P,
\]

by dimensional analysis. This is because we know that \( m_{\text{soft}} \) must vanish in the limit \( \langle F \rangle \to 0 \) where supersymmetry is unbroken, and also in the limit \( M_P \to \infty \) (corresponding to \( G_{\text{Newton}} \to 0 \) ) in which gravity becomes irrelevant. For \( m_{\text{soft}} \) of order a few hundred GeV, one would therefore expect that the scale associated with the origin of supersymmetry breaking in the hidden sector should be roughly \( \sqrt{\langle F \rangle} \sim 10^{10} \) or \( 10^{11} \) GeV. Another possibility is that the supersymmetry breaking order parameter is a gaugino condensate \( \langle 0 | \lambda^a \lambda^b | 0 \rangle = \delta^{ab} \Lambda^3 \neq 0 \). If the composite field \( \lambda^a \lambda^b \) is part of an auxiliary field \( F \) for some (perhaps composite) chiral superfield, then by dimensional analysis we expect supersymmetry breaking soft terms of order

\[
m_{\text{soft}} \sim \Lambda^3 / M_P^2,
\]

with, effectively, \( \langle F \rangle \sim \Lambda^3 / M_P \). In that case, the scale associated with dynamical supersymmetry breaking should be more like \( \Lambda \sim 10^{13} \) GeV.

A second possibility is that the flavor-blind mediating interactions for supersymmetry breaking are the ordinary electroweak and QCD gauge interactions. In this gauge-mediated supersymmetry breaking (GMSB) scenario, the MSSM soft terms come from loop diagrams involving some messenger particles. The messengers are new chiral supermultiplets that couple to a supersymmetry-breaking VEV \( \langle F \rangle \), and also have \( SU(3)_C \times SU(2)_L \times U(1)_Y \) interactions, which provide the necessary connection to the MSSM. Then, using dimensional analysis, one estimates for the MSSM soft terms

\[
m_{\text{soft}} \sim \frac{\alpha_a}{4\pi} \frac{\langle F \rangle}{M_{\text{mess}}},
\]

where the \( \alpha_a / 4\pi \) is a loop factor for Feynman diagrams involving gauge interactions, and \( M_{\text{mess}} \) is a characteristic scale of the masses of the messenger fields. So if \( M_{\text{mess}} \) and \( \sqrt{\langle F \rangle} \) are roughly comparable, then the scale of supersymmetry breaking can be as low as about \( \sqrt{\langle F \rangle} \sim 10^4 \) GeV (much lower than in the gravity-mediated case!) to give \( m_{\text{soft}} \) of the right order of magnitude.

6.5 The goldstino and the gravitino

As shown in section 6.1, the spontaneous breaking of global supersymmetry implies the existence of a massless Weyl fermion, the goldstino. The goldstino is the fermionic component of the supermultiplet whose auxiliary field obtains a VEV.
Thus the gravitino should be thought of as the “gauge” field of local supersymmetry transformations [compare eq. (3.55)]. As long as supersymmetry is unbroken, the graviton and the gravitino are

\[ \partial_\mu J^\mu = (\sigma^\mu \partial_\mu \tilde{G})_\alpha + \partial_\mu J^\mu + \ldots \]

(6.28)

where \( j_\alpha^\mu \) is the part of the supercurrent that involves all of the other supermultiplets, and the ellipses represent other contributions of the goldstino supermultiplet to \( \partial_\mu J_\alpha^\mu \), which we can ignore. [The first term in eq. (6.28) comes from the second term in eq. (3.76), using the equation of motion \( F_i = -W_i^* \) for the goldstino’s auxiliary field.] This equation of motion for the goldstino field allows us to write an effective Lagrangian

\[ \mathcal{L}_{\text{goldstino}} = -i \overline{G}^{\mu} \partial_\mu \tilde{G} - \frac{1}{\langle F \rangle} (\tilde{G} \partial_\mu j^\mu + \text{c.c.}), \]

(6.29)

which describes the interactions of the goldstino with all of the other fermion-boson pairs [125]. In particular, since \( j_\alpha^\mu = (\sigma^\nu \partial^\mu \psi)_{\alpha} \partial_\mu \phi^{\pm \ast} + \sigma^\nu \partial^\mu \phi^{\pm \ast} \delta^\nu_5 F^\alpha_{\mu \nu} / 2 \sqrt{2} + \ldots \), there are goldstino-scalar-chiral fermion and goldstino-gaugino-gauge boson vertices as shown in Figure 6.2. Since this derivation depends only on supercurrent conservation, eq. (6.29) holds independently of the details of how supersymmetry breaking is communicated from \( \langle F \rangle \) to the MSSM sector fields (\( \phi, \psi \)) and (\( \lambda^a, A^a \)). It may appear strange at first that the interaction couplings in eq. (6.29) get larger in the limit \( \langle F \rangle \to 0 \), and the interaction is well-defined in that limit. Nevertheless, for fixed values of \( m_\phi^2 - m_\psi^2 \) and \( m_\lambda^2 - m_A^2 \), the interaction term in eq. (6.29) can be phenomenologically important if \( \langle F \rangle \) is not too large [125, 128].

The above remarks apply to the breaking of global supersymmetry. However, taking into account gravity, supersymmetry must be promoted to a local symmetry. This means that the spinor parameter \( e_\alpha \), which first appeared in section 3.1, is no longer a constant, but can vary from point to point in spacetime. The resulting locally supersymmetric theory is called supergravity [129, 130]. It necessarily unifies the spacetime symmetries of ordinary general relativity with local supersymmetry transformations. In supergravity, the spin-2 graviton has a spin-3/2 fermion superpartner called the gravitino, which we will denote \( \tilde{\Psi}_\mu^\alpha \). The gravitino has odd \( R \)-parity (\( P_R = -1 \)), as can be seen from the definition eq. (5.11). It carries both a vector index (\( \mu \)) and a spinor index (\( \alpha \)), and transforms inhomogeneously under local supersymmetry transformations:

\[ \delta \tilde{\Psi}_\mu^\alpha = \partial_\mu e_\alpha + \ldots \]

(6.30)

Thus the gravitino should be thought of as the “gauge” field of local supersymmetry transformations [compare eq. (3.55)]. As long as supersymmetry is unbroken, the graviton and the gravitino are

1More generally, if supersymmetry is spontaneously broken by VEVs for several auxiliary fields \( F_i \) and \( D^a \), then one should make the replacement \( \langle F \rangle \to (\sum_i |\langle F_i \rangle|^2 + \frac{1}{2} \sum_a (\langle D^a \rangle)^2)^{1/2} \) everywhere in the following.
both massless, each with two spin helicity states. Once supersymmetry is spontaneously broken, the gravitino acquires a mass by absorbing (“eating”) the goldstino, which becomes its longitudinal (helicity $\pm 1/2$) components. This is called the super-Higgs mechanism, and it is analogous to the ordinary Higgs mechanism for gauge theories, by which the $W^\pm$ and $Z^0$ gauge bosons in the Standard Model gain mass by absorbing the Nambu-Goldstone bosons associated with the spontaneously broken electroweak gauge invariance. The massive spin-3/2 gravitino now has four helicity states, of which two were originally assigned to the would-be goldstino. The gravitino mass is traditionally called $m_{3/2}$, and in the case of $F$-term breaking it can be estimated as

$$m_{3/2} \sim \langle F \rangle / M_P,$$

(6.31)

This follows simply from dimensional analysis, since $m_{3/2}$ must vanish in the limits that supersymmetry is restored ($\langle F \rangle \to 0$) and that gravity is turned off ($M_P \to \infty$). Equation (6.31) implies very different expectations for the mass of the gravitino in gravity-mediated and in gauge-mediated models, because they usually make very different predictions for $\langle F \rangle$.

In the Planck-scale-mediated supersymmetry breaking case, the gravitino mass is comparable to the masses of the MSSM sparticles [compare eqs. (6.25) and (6.31)]. Therefore $m_{3/2}$ is expected to be at least of order 100 GeV or so. Its interactions will be of gravitational strength, so the gravitino will not play any role in collider physics, but it can be important in cosmology. If it is the LSP, then it is stable and its primordial density could easily exceed the critical density, causing the universe to become matter-dominated too early. Even if it is not the LSP, the gravitino can cause problems unless its density is diluted by inflation at late times, or it decays sufficiently rapidly.

In contrast, gauge-mediated supersymmetry breaking models predict that the gravitino is much lighter than the MSSM sparticles as long as $M_{mess} \ll M_P$. This can be seen by comparing eqs. (6.27) and (6.31). The gravitino is almost certainly the LSP in this case, and all of the MSSM sparticles will eventually decay into final states that include it. Naively, one might expect that these decays are extremely slow. However, this is not necessarily true, because the gravitino inherits the non-gravitational interactions of the goldstino it has absorbed. This means that the gravitino, or more precisely its longitudinal (goldstino) components, can play an important role in collider physics experiments. The mass of the gravitino can generally be ignored for kinematic purposes, as can its transverse (helicity $\pm 3/2$) components, which really do have only gravitational interactions. Therefore in collider phenomenology discussions one may interchangeably use the same symbol $\tilde{G}$ for the goldstino and for the gravitino of which it is the longitudinal (helicity $\pm 1/2$) part. By using the effective Lagrangian eq. (6.29), one can compute that the decay rate of any sparticle $\tilde{X}$ into its Standard Model partner $X$ plus a goldstino/gravitino $\tilde{G}$ is

$$\Gamma(\tilde{X} \to X\tilde{G}) = \frac{m_{\tilde{X}}^5}{16\pi F^2} \left(1 - \frac{m_X^2}{m_{\tilde{X}}^2} \right)^4.$$  

(6.32)

This corresponds to either Figure 6.2a or 6.2b, with $(\tilde{X}, X) = (\phi, \psi)$ or $(\lambda, A)$ respectively. One factor $(1 - m_X^2/m_{\tilde{X}}^2)^2$ came from the derivatives in the interaction term in eq. (6.29) evaluated for on-shell final states, and another such factor comes from the kinematic phase space integral with $m_{3/2} \ll m_{\tilde{X}}, m_X$.

If the supermultiplet containing the goldstino and $\langle F \rangle$ has canonically normalized kinetic terms, and the tree-level vacuum energy is required to vanish, then the estimate eq. (6.31) is sharpened to

$$m_{3/2} = \langle F \rangle / \sqrt{3} M_P.$$  

(6.33)

In that case, one can rewrite eq. (6.32) as

$$\Gamma(\tilde{X} \to X\tilde{G}) = \frac{m_{\tilde{X}}^5}{48\pi M_P^2 m_{3/2}^2} \left(1 - \frac{m_X^2}{m_{\tilde{X}}^2} \right)^4.$$  

(6.34)
and this is how the formula is sometimes presented, although it is less general since it assumes eq. \((6.33)\). The decay width is larger for smaller \(\langle F \rangle\), or equivalently for smaller \(m_{3/2}\), if the other masses are fixed. If \(\tilde{X}\) is a mixture of superpartners of different Standard Model particles \(X\), then each partial width in eq. \((6.32)\) should be multiplied by a suppression factor equal to the square of the cosine of the appropriate mixing angle. If \(m_{\tilde{X}}\) is of order 100 GeV or more, and \(\sqrt{\langle F \rangle} < \text{few} \times 10^6\) GeV [corresponding to \(m_{3/2}\) less than roughly 1 keV according to eq. \((6.33)\)], then the decay \(\tilde{X} \rightarrow X\tilde{G}\) can occur quickly enough to be observed in a modern collider detector. This implies some interesting phenomenological signatures, which we will discuss further in sections 8.5 and 9.

We now turn to a more systematic analysis of the way in which the MSSM soft terms arise.

### 6.6 Planck-scale-mediated supersymmetry breaking models

Consider the class of models defined by the feature that the spontaneous supersymmetry-breaking sector connects with our MSSM only (or dominantly) through gravitational-strength interactions \([133, 134]\). This means that the supergravity effective Lagrangian contains non-renormalizable terms that communicate between the two sectors and are suppressed by powers of the Planck mass \(M_P\). These will include

\[
\mathcal{L}_{\text{NR}} = -\frac{1}{M_P^2} F F^* k_{ij} \phi_i \phi_j + \text{c.c.}
\]

where \(F\) is the auxiliary field for a chiral supermultiplet in the hidden sector, and \(\phi_i\) and \(\lambda^a\) are the scalar and gaugino fields in the MSSM, and \(f^a\), \(g^{ij}\), and \(k_{ij}\) are dimensionless constants. By themselves, the terms in eq. \((6.35)\) are not supersymmetric, but it is possible to show that they are part of a non-renormalizable supersymmetric Lagrangian (see Appendix) that contains other terms that we may ignore. Now if one assumes that \(\sqrt{\langle F \rangle} \sim 10^{10}\) or \(10^{11}\) GeV, then \(\mathcal{L}_{\text{NR}}\) will give us nothing other than a Lagrangian of the form \(\mathcal{L}_{\text{soft}}\) in eq. \((1.1)\), with MSSM soft terms of order \(m_{\text{soft}} \sim \langle F \rangle / M_P = \text{a few hundred GeV}\).

Note that couplings of the form \(\mathcal{L}_{\text{maybe soft}}\) in eq. \((1.2)\) do not arise from eq. \((6.35)\). They actually are expected to occur, but the largest term from which they could come is:

\[
\mathcal{L} = -\frac{1}{M_P^2} F F^* x_{i}^{jk} \phi_i \phi_j + \text{c.c.},
\]

so in this model framework they are of order \(\langle F \rangle^2 / M_P^3 \sim m_{\text{soft}}^2 / M_P\), and therefore negligible.

The parameters \(f^a\), \(k_{ij}\), \(g^{ij}\), and \(\mu^{ij}\) in \(\mathcal{L}_{\text{NR}}\) are to be determined by the underlying theory. This is a difficult enterprise in general, but a dramatic simplification occurs if one assumes a “minimal” form for the normalization of kinetic terms and gauge interactions in the full, non-renormalizable supergravity Lagrangian (see Appendix). In that case, there is a common \(f_a\) for the three gauginos; \(k_{ij} = k\delta_{ij}\) is the same for all scalars; and the other couplings are proportional to the corresponding superpotential parameters, so that \(g^{ij} = \alpha g^{ij}\) and \(\mu^{ij} = \beta \mu^{ij}\) with universal dimensionless constants \(\alpha\) and \(\beta\). Then the soft terms in \(\mathcal{L}_{\text{soft}}\) are all determined by just four parameters:

\[
m_{1/2} = f \frac{\langle F \rangle}{M_P}, \quad m_0^2 = k \frac{|\langle F \rangle|^2}{M_P^2}, \quad A_0 = \alpha \frac{\langle F \rangle}{M_P}, \quad B_0 = \beta \frac{\langle F \rangle}{M_P}.
\]

In terms of these, the parameters appearing in eq. \((5.12)\) are:

\[
M_3 = M_2 = M_1 = m_{1/2},
\]
\[
\begin{align*}
\mathcal{m}_Q^2 &= \mathcal{m}_U^2 =\mathcal{m}_d^2 = \mathcal{m}_l^2 = \mathcal{m}_e^2 = \mathcal{m}_1^2, \\
\mathcal{a}_u &= A_0 y_u, \\
\mathcal{a}_d &= A_0 y_d, \\
\mathcal{a}_e &= A_0 y_e, \\
\mathcal{b} &= B_0 \mu,
\end{align*}
\]

(6.39) (6.40) (6.41)

at a renormalization scale \( Q \approx M_P \). It is a matter of some controversy whether the assumptions going into this parameterization are well-motivated on purely theoretical grounds,\(^1\) but from a phenomenological perspective they are clearly very nice. This framework successfully evades the most dangerous types of flavor changing and CP violation as discussed in section 5.4. In particular, eqs. (6.39) and (6.40) are just stronger versions of eqs. (5.18) and (5.19), respectively. If \( m_{1/2}, A_0 \) and \( B_0 \) all have the same complex phase, then eq. (5.20) will also be satisfied.

Equations (6.38)-(6.41) also have the virtue of being highly predictive. [Of course, eq. (6.41) is content-free unless one can relate \( B_0 \) to the other parameters in some non-trivial way.] As discussed in sections and 5.4 and 5.5, they should be applied as RG boundary conditions at the scale \( M_U \). The RG evolution of the soft parameters down to the electroweak scale will then allow us to predict the entire MSSM spectrum in terms of just five parameters \( m_{1/2}, m_0, A_0, B_0, \) and \( \mu \) (plus the already-measured gauge and Yukawa couplings of the MSSM). A popular approximation is to start this RG running from the unification scale \( M_U \approx 2 \times 10^{16} \text{ GeV} \) instead of \( M_P \). The reason for this is more practical than principled; the apparent unification of gauge couplings gives us a strong hint that we know something about how the RG equations behave up to \( M_U \), but unfortunately gives us little guidance about what to expect at scales between \( M_U \) and \( M_P \). The errors made in neglecting these effects are proportional to a loop suppression factor times \( \ln(M_P/M_U) \). These corrections hopefully can be partly absorbed into a redefinition of \( m_0^2, m_{1/2}, A_0 \) and \( B_0 \) at \( M_U \), but in many cases can lead to other important effects.\(^{135}\) The framework described in the above few paragraphs has been the subject of the bulk of phenomenological studies of supersymmetry. It is sometimes referred to as the minimal supergravity (MSUGRA) or supergravity-inspired scenario for the soft terms. A few examples of the many useful numerical RG studies of the MSSM spectrum that have been performed in this framework can be found in ref. \(^{136}\).

Particular models of gravity-mediated supersymmetry breaking can be even more predictive, relating some of the parameters \( m_{1/2}, m_0^2, A_0 \) and \( B_0 \) to each other and to the mass of the gravitino \( m_{3/2} \). For example, three popular kinds of models for the soft terms are:

- Dilaton-dominated: \(^{137}\) \( m_0^2 = m_{3/2}^2, \quad m_{1/2} = -A_0 = \sqrt{3} m_{3/2}. \)
- Polonyi: \(^{138}\) \( m_0^2 = m_{3/2}^2, \quad A_0 = (3 - \sqrt{3}) m_{3/2}, \quad m_{1/2} = \mathcal{O}(m_{3/2}). \)
- “No-scale”: \(^{139}\) \( m_{1/2} \gg m_0, A_0, m_{3/2}. \)

Dilaton domination arises in a particular limit of superstring theory. While it appears to be highly predictive, it can easily be generalized in other limits \(^{140}\). The Polonyi model has the advantage of being the simplest possible model for supersymmetry breaking in the hidden sector, but it is rather ad hoc and does not seem to have a special place in grander schemes like superstrings. The “no-scale” limit may appear in a low-energy limit of superstrings in which the gravitino mass scale is undetermined at tree-level (hence the name). It implies that the gaugino masses dominate over other sources of supersymmetry breaking near \( M_P \). As we saw in section 5.5, RG evolution feeds \( m_{1/2} \) into the squark, slepton, and Higgs squared-mass parameters with sufficient magnitude to give acceptable phenomenology at the electroweak scale. More recent versions of the no-scale scenario, however, also can give significant \( A_0 \) and \( m_0^2 \) at \( M_P \). In many cases \( B_0 \) can also be predicted in terms of the other parameters, but this is quite sensitive to model assumptions. For phenomenological studies, \( m_{1/2}, \)

\(^1\)The familiar flavor blindness of gravity expressed in Einstein’s equivalence principle does not, by itself, tell us anything about the form of eq. (6.35), and in particular need not imply eqs. (6.38)-(6.40). (See Appendix.)
\( m_0^2, A_0 \) and \( B_0 \) are usually just taken to be imperfect but convenient independent parameters of our ignorance of the supersymmetry breaking mechanism.

### 6.7 Gauge-mediated supersymmetry breaking models

In gauge-mediated supersymmetry breaking (GMSB) models \[141, 142\], the ordinary gauge interactions, rather than gravity, are responsible for the appearance of soft supersymmetry breaking in the MSSM. The basic idea is to introduce some new chiral supermultiplets, called messengers, that couple to the ultimate source of supersymmetry breaking, and also couple indirectly to the \((s)\)quarks and \((s)\)leptons and Higgs(inos) of the MSSM through the ordinary SU(3)\(_C\) × SU(2)\(_L\) × U(1)\(_Y\) gauge boson and gaugino interactions. There is still gravitational communication between the MSSM and the source of supersymmetry breaking, of course, but that effect is now relatively unimportant compared to the gauge interaction effects.

In contrast to Planck-scale mediation, GMSB can be understood entirely in terms of loop effects in a renormalizable framework. In the simplest such model, the messenger fields are a set of left-handed chiral supermultiplets \( q, \bar{q}, \ell, \bar{\ell} \) transforming under SU(3)\(_C\) × SU(2)\(_L\) × U(1)\(_Y\) as

\[
q \sim (3, 1, -\frac{1}{3}), \quad \bar{q} \sim (\bar{3}, 1, \frac{1}{3}), \quad \ell \sim (1, 2, \frac{1}{2}), \quad \bar{\ell} \sim (1, 2, -\frac{1}{2}).
\] (6.42)

These supermultiplets contain messenger quarks \( \psi_q, \psi_{\bar{q}} \) and scalar quarks \( q, \bar{q} \) and messenger leptons \( \psi_{\ell}, \psi_{\bar{\ell}} \) and scalar leptons \( \ell, \bar{\ell} \). All of these particles must get very large masses so as not to have been discovered already. Assume they do so by coupling to a gauge-singlet chiral supermultiplet \( S \) through a superpotential:

\[
W_{\text{mess}} = y_2 S \ell \bar{\ell} + y_3 S q \bar{q}.
\] (6.43)

The scalar component of \( S \) and its auxiliary \((F\text{-term})\) component are each supposed to acquire VEVs, denoted \( \langle S \rangle \) and \( \langle F_S \rangle \) respectively. This can be accomplished either by putting \( S \) into an O’Raifertaigh-type model \[141\], or by a dynamical mechanism \[142\]. Exactly how this happens is an interesting and important question, without a clear answer at present. Here, we will simply parameterize our ignorance of the precise mechanism of supersymmetry breaking by asserting that \( S \) participates in another part of the superpotential, call it \( W_{\text{breaking}} \), which provides for the necessary spontaneous breaking of supersymmetry.

Let us now consider the mass spectrum of the messenger fermions and bosons. The fermionic messenger fields pair up to get mass terms:

\[
\mathcal{L} = -y_2 \langle S \rangle \psi_\ell \psi_{\bar{\ell}} - y_3 \langle S \rangle \psi_q \psi_{\bar{q}} + \text{c.c.}
\] (6.44)

as in eq. (3.51). Meanwhile, their scalar messenger partners \( \ell, \bar{\ell} \) and \( q, \bar{q} \) have a scalar potential given by (neglecting \( D\text{-term} \) contributions, which do not affect the following discussion):

\[
V = \left| \frac{\delta W_{\text{mess}}}{\delta \ell} \right|^2 + \left| \frac{\delta W_{\text{mess}}}{\delta \bar{\ell}} \right|^2 + \left| \frac{\delta W_{\text{mess}}}{\delta q} \right|^2 + \left| \frac{\delta W_{\text{mess}}}{\delta \bar{q}} \right|^2 + \left| \frac{\delta}{\delta S} (W_{\text{mess}} + W_{\text{breaking}}) \right|^2
\] (6.45)

as in eq. (3.50). Now, suppose that, at the minimum of the potential,

\[
\langle S \rangle \neq 0,
\] (6.46)

\[
\langle \delta W_{\text{breaking}}/\delta S \rangle = -\langle F_S^2 \rangle \neq 0,
\] (6.47)

\[
\langle \delta W_{\text{mess}}/\delta S \rangle = 0.
\] (6.48)
Replacing $S$ and $F_S$ by their VEVs, one finds quadratic mass terms in the potential for the messenger scalar leptons:

$$V = |y_2 \langle S \rangle|^2 (|\ell|^2 + |\mathbf{7}|^2) + |y_3 \langle S \rangle|^2 (|q|^2 + |\mathbf{7}|^2)$$

$$- (y_2 \langle F_S \rangle \ell \ell + y_3 \langle F_S \rangle q q + c.c.)$$

+ quartic terms.  

The first line in eq. (6.49) represents supersymmetric mass terms that go along with eq. (6.44), while the second line consists of soft supersymmetry-breaking masses. The complex scalar messengers $\ell, \overline{\ell}$ thus obtain a squared-mass matrix equal to:

$$\begin{pmatrix} |y_2 \langle S \rangle|^2 & -y^*_2 \langle F_S^* \rangle \\ -y_2 \langle F_S \rangle & |y_2 \langle F_S \rangle|^2 \end{pmatrix}$$

(6.50)

with squared mass eigenvalues $|y_2 \langle S \rangle|^2 \pm |y_2 \langle F_S \rangle|$. In just the same way, the scalars $q, \overline{q}$ get squared masses $|y_3 \langle S \rangle|^2 \pm |y_3 \langle F_S \rangle|$.

So far, we have found that the effect of supersymmetry breaking is to split each messenger supermultiplet pair apart:

$$\ell, \overline{\ell} : \quad m^2_{\text{fermions}} = |y_2 \langle S \rangle|^2, \quad m^2_{\text{scalars}} = |y_2 \langle S \rangle|^2 \pm |y_2 \langle F_S \rangle|,$$

$$q, \overline{q} : \quad m^2_{\text{fermions}} = |y_3 \langle S \rangle|^2, \quad m^2_{\text{scalars}} = |y_3 \langle S \rangle|^2 \pm |y_3 \langle F_S \rangle|.$$  

The supersymmetry violation apparent in this messenger spectrum for $\langle F_S \rangle \neq 0$ is communicated to the MSSM sparticles through radiative corrections. The MSSM gauginos obtain masses from the 1-loop Feynman diagram shown in Figure 6.3. The scalar and fermion lines in the loop are messenger fields. Recall that the interaction vertices in Figure 6.3 are of gauge coupling strength even though they do not involve gauge bosons; compare Figure 3.3g. In this way, gauge-mediation provides that $q, \overline{q}$ messenger loops give masses to the gluino and the bino, and $\ell, \overline{\ell}$ messenger loops give masses to the wino and bino fields. Computing the 1-loop diagrams, one finds [142] that the resulting MSSM gaugino masses are given by

$$M_a = \frac{\alpha_a}{4\pi} \Lambda, \quad (a = 1, 2, 3),$$

(6.53)

in the normalization for $\alpha_a$ discussed in section 5.4 where we have introduced a mass parameter

$$\Lambda \equiv \langle F_S \rangle / \langle S \rangle.$$  

(6.54)

(Note that if $\langle F_S \rangle$ were 0, then $\Lambda = 0$ and the messenger scalars would be degenerate with their fermionic superpartners and there would be no contribution to the MSSM gaugino masses.) In contrast, the corresponding MSSM gauge bosons cannot get a corresponding mass shift, since they are protected by gauge invariance. So supersymmetry breaking has been successfully communicated to the MSSM ("visible sector"). To a good approximation, eq. (6.53) holds for the running gaugino masses at an RG scale $Q_0$ corresponding to the average characteristic mass of the heavy messenger particles, roughly of
order $M_{\text{mess}} \sim y_I \langle S \rangle$ for $I = 2, 3$. The running mass parameters can then be RG-evolved down to the electroweak scale to predict the physical masses to be measured by future experiments.

The scalars of the MSSM do not get any radiative corrections to their masses at one-loop order. The leading contribution to their masses comes from the two-loop graphs shown in Figure 6.4 with the messenger fermions (heavy solid lines) and messenger scalars (heavy dashed lines) and ordinary gauge bosons and gauginos running around the loops. By computing these graphs, one finds that each MSSM scalar $\phi_i$ gets a squared mass given by:

$$m_{\phi_i}^2 = 2\Lambda^2 \left[ \left( \frac{\alpha_3}{4\pi} \right)^2 C_3(i) + \left( \frac{\alpha_2}{4\pi} \right)^2 C_2(i) + \left( \frac{\alpha_1}{4\pi} \right)^2 C_1(i) \right],$$

with the quadratic Casimir invariants $C_a(i)$ as in eqs. (5.27)-(5.30). The squared masses in eq. (6.55) are positive (fortunately!).

The terms $a_u, a_d, a_e$ arise first at two-loop order, and are suppressed by an extra factor of $\alpha_a/4\pi$ compared to the gaugino masses. So, to a very good approximation one has, at the messenger scale,

$$a_u = a_d = a_e = 0,$$

(6.56)
a significantly stronger condition than eq. (6.49). Again, eqs. (6.55) and (6.56) should be applied at an RG scale equal to the average mass of the messenger fields running in the loops. However, evolving the RG equations down to the electroweak scale generates non-zero $a_u, a_d,$ and $a_e$ proportional to the corresponding Yukawa matrices and the non-zero gaugino masses, as indicated in section 5.5. These will only be large for the third-family squarks and sleptons, in the approximation of eq. (5.2). The parameter $b$ may also be taken to vanish near the messenger scale, but this is quite model-dependent, and in any case $b$ will be non-zero when it is RG-evolved to the electroweak scale. In practice, $b$ can be fixed in terms of the other parameters by the requirement of correct electroweak symmetry breaking, as discussed below in section 7.1.

Because the gaugino masses arise at one-loop order and the scalar squared-mass contributions appear at two-loop order, both eq. (6.53) and (6.55) correspond to the estimate eq. (6.27) for $m_{\text{soft}}$, with $M_{\text{mess}} \sim y_I \langle S \rangle$. Equations (6.53) and (6.55) hold in the limit of small $\langle F_S \rangle / y_I \langle S \rangle^2$, corresponding to mass splittings within each messenger supermultiplet that are small compared to the overall messenger mass scale. The sub-leading corrections in an expansion in $\langle F_S \rangle / y_I \langle S \rangle^2$ turn out [143] to be quite small unless there are very large messenger mass splittings.

The model we have described so far is often called the minimal model of gauge-mediated supersymmetry breaking. Let us now generalize it to a more complicated messenger sector. Suppose that $q, \bar{q}$
and $\ell, \overline{\ell}$ are replaced by a collection of messengers $\Phi_I, \overline{\Phi}_I$ with a superpotential

$$W_{\text{mess}} = \sum_I y_I S \Phi_I \overline{\Phi}_I.$$  \hspace{1cm} (6.57)

The bar is used to indicate that the left-handed chiral superfields $\Phi_I$ transform as the complex conjugate representations of the left-handed chiral superfields $\overline{\Phi}_I$. Together they are said to form a “vector-like” (real) representation of the Standard Model gauge group. As before, the fermionic components of each pair $\Phi_I$ and $\overline{\Phi}_I$ pair up to get squared masses $|y_I \langle S \rangle|^2$ and their scalar partners mix to get squared masses $|y_I \langle S \rangle|^2 \pm |y_I \langle F_S \rangle|$. The MSSM gaugino mass parameters induced are now

$$M_a = \frac{\alpha_a}{4\pi} \Lambda \sum_I n_a(I) \quad (a = 1, 2, 3)$$  \hspace{1cm} (6.58)

where $n_a(I)$ is the Dynkin index for each $\Phi_I + \overline{\Phi}_I$, in a normalization where $n_3 = 1$ for a $3 + \overline{3}$ of $SU(3)_C$ and $n_2 = 1$ for a pair of doublets of $SU(2)_L$. For $U(1)_Y$, one has $n_1 = 6Y^2/5$ for each messenger pair with weak hypercharges $\pm Y$. In computing $n_1$ one must remember to add up the contributions for each component of an $SU(3)_C$ or $SU(2)_L$ multiplet. So, for example, $(n_1, n_2, n_3) = (2/5, 0, 1)$ for $q + \overline{q}$ and $(n_1, n_2, n_3) = (3/5, 1, 0)$ for $\ell + \overline{\ell}$. Thus the total is $\sum_I (n_1, n_2, n_3) = (1, 1, 1)$ for the minimal model, so that eq. (6.58) is in agreement with eq. (6.53). On general group-theoretic grounds, $n_2$ and $n_3$ must be integers, and $n_1$ is always an integer multiple of $1/5$ if fractional electric charges are confined.

The MSSM scalar masses in this generalized gauge mediation framework are now:

$$m_{\tilde{\phi}_i}^2 = 2\Lambda^2 \left[ \left( \frac{\alpha_3}{4\pi} \right)^2 C_3(i) \sum_I n_3(I) + \left( \frac{\alpha_2}{4\pi} \right)^2 C_2(i) \sum_I n_2(I) + \left( \frac{\alpha_1}{4\pi} \right)^2 C_1(i) \sum_I n_1(I) \right].$$  \hspace{1cm} (6.59)

In writing eqs. (6.58) and (6.59) as simple sums, we have implicitly assumed that the messengers are all approximately equal in mass, with

$$M_{\text{mess}} \approx y_I \langle S \rangle.$$  \hspace{1cm} (6.60)

Equation (6.59) is still not a bad approximation if the $y_I$ are not very different from each other, because the dependence of the MSSM mass spectrum on the $y_I$ is only logarithmic (due to RG running) for fixed $\Lambda$. However, if large hierarchies in the messenger masses are present, then the additive contributions to the gaugino masses and scalar squared masses from each individual messenger multiplet $I$ should really instead be incorporated at the mass scale of that messenger multiplet. Then RG evolution is used to run these various contributions down to the electroweak or TeV scale; the individual messenger contributions to scalar and gaugino masses as indicated above can be thought of as threshold corrections to this RG running.

Messengers with masses far below the GUT scale will affect the running of gauge couplings and might therefore be expected to ruin the apparent unification shown in Figure 5.8. However, if the messengers come in complete multiplets of the $SU(5)$ global symmetry\(^1\) that contains the Standard Model gauge group, and are not very different in mass, then approximate unification of gauge couplings will still occur when they are extrapolated up to the same scale $M_U$ (but with a larger unified value for the gauge couplings at that scale). For this reason, a popular class of models is obtained by taking the messengers to consist of $N_5$ copies of the $\mathbf{5} + \overline{\mathbf{5}}$ of $SU(5)$, resulting in

$$\sum_I n_1(I) = \sum_I n_2(I) = \sum_I n_3(I) = N_5.$$  \hspace{1cm} (6.61)

\(^1\)This $SU(5)$ may or may not be promoted to a local gauge symmetry at the GUT scale. For our present purposes, it is used only as a classification scheme, since the global $SU(5)$ symmetry is only approximate in the effective theory at the (much lower) messenger mass scale where gauge mediation takes place.
Figure 6.5: The separation of the supersymmetry-breaking sector from the MSSM sector could take place along a hidden spatial dimension, as in the simple example shown here. The branes are 4-dimensional parallel spacetime hypersurfaces in a 5-dimensional spacetime.

Equations (6.58) and (6.59) then reduce to

\[ M_a = \frac{\alpha_a}{4\pi} \Lambda N_5, \]
\[ m_{\phi_i}^2 = 2\Lambda^2 N_5 \sum_{a=1}^{3} C_a(i) \left( \frac{\alpha_a}{4\pi} \right)^2, \]

since now there are \( N_5 \) copies of the minimal messenger sector particles running around the loops. For example, the minimal model in eq. (6.42) corresponds to \( N_5 = 1 \). A single copy of \( 10 + \overline{10} \) of \( SU(5) \) has Dynkin indices \( \sum_I n_a(I) = 3 \), and so can be substituted for 3 copies of \( 5 + \overline{5} \). (Other combinations of messenger multiplets can also preserve the apparent unification of gauge couplings.) Note that the gaugino masses scale like \( N_5 \), while the scalar masses scale like \( \sqrt{N_5} \). This means that sleptons and squarks will tend to be lighter relative to the gauginos for larger values of \( N_5 \) in non-minimal models. However, if \( N_5 \) is too large, then the running gauge couplings will diverge before they can unify at \( M_U \).

For messenger masses of order \( 10^6 \) GeV or less, for example, one needs \( N_5 \leq 4 \).

There are many other possible generalizations of the basic gauge-mediation scenario as described above. An important general expectation in these models is that the strongly interacting sparticles (squarks, gluino) should be heavier than weakly interacting sparticles (sleptons, bino, winos), simply because of the hierarchy of gauge couplings \( \alpha_3 > \alpha_2 > \alpha_1 \). The common feature that makes all of these models attractive is that the masses of the squarks and sleptons depend only on their gauge quantum numbers, leading automatically to the degeneracy of squark and slepton masses needed for suppression of flavor-changing effects. But the most distinctive phenomenological prediction of gauge-mediated models may be the fact that the gravitino is the LSP. This can have crucial consequences for both cosmology and collider physics, as we will discuss further in sections 8.5 and 9.

6.8 Extra-dimensional and anomaly-mediated supersymmetry breaking

It is also possible to take the partitioning of the MSSM and supersymmetry breaking sectors shown in fig. 6.1 seriously as geography. This can be accomplished by assuming that there are extra spatial dimensions of the Kaluza-Klein or warped type \[ \text{[144]} \], so that a physical distance separates the visible and hidden\(^{1}\) sectors. This general idea opens up numerous possibilities, which are hard to classify in a detailed way. For example, string theory suggests six such extra dimensions, with a staggeringly huge number of possible solutions.

Many of the more recently popular models used to explore this extra-dimensional mediated supersymmetry breaking (the acronym XMSB is tempting) use just one single hidden extra dimension with the MSSM chiral supermultiplets confined to one 4-dimensional spacetime brane and the supersymmetry-breaking sector confined to a parallel brane a distance \( R_5 \) away, separated by a 5-dimensional bulk, as in fig. 6.5. Using this as an illustration, the dangerous flavor-violating terms proportional to \( g^{ijk} \) and \( k_j^i \) in eq. (6.35) are suppressed by factors like \( e^{-R_5 M_5} \), where \( R_5 \) is the size of

\(^{1}\)The name “sequestered” is often used instead of “hidden” in this context.
the 5th dimension and $M_5$ is the 5-dimensional fundamental (Planck) scale, and it is assumed that the MSSM chiral supermultiplets are confined to their brane. Therefore, it should be enough to require that $R_5 M_5 \gg 1$, in other words that the size of the 5th dimension (or, more generally, the volume of the compactified space) is relatively large in units of the fundamental length scale. Thus the suppression of flavor-violating effects does not require any fine-tuning or extreme hierarchies, because it is exponential.

One possibility is that the gauge supermultiplets of the MSSM propagate in the bulk, and so mediate supersymmetry breaking \[145\]-\[148\]. This mediation is direct for gauginos, with

$$M_a \sim \frac{\langle F \rangle}{M_5 (R_5 M_5)},$$

but is loop-suppressed for the soft terms involving scalars. This implies that in the simplest version of the idea, often called “gaugino mediation”, soft supersymmetry breaking is dominated by the gaugino masses. The phenomenology is therefore quite similar to that of the “no-scale” boundary conditions mentioned in subsection 6.6 in the context of PMSB models. Scalar squared masses and the scalar cubic couplings come from renormalization group running down to the electroweak scale. It is useful to keep in mind that gaugino mass dominance is really the essential feature that defeats flavor violation, so it may well turn out to be more robust than any particular model that provides it.

It is also possible that the gauge supermultiplet fields are also confined to the MSSM brane, so that the transmission of supersymmetry breaking is due entirely to supergravity effects. This leads to anomaly-mediated supersymmetry breaking (AMSB) \[149\], so-named because the resulting MSSM soft terms can be understood in terms of the anomalous violation of a local superconformal invariance, an extension of scale invariance. In one formulation of supergravity \[130\]. Newton’s constant (or equivalently, the Planck mass scale) is set by the VEV of a scalar field $\phi$ that is part of a non-dynamical chiral supermultiplet (called the “conformal compensator”). As a gauge fixing, this field obtains a VEV of $\langle \phi \rangle = 1$, spontaneously breaking the local superconformal invariance. Now, in the presence of spontaneous supersymmetry breaking $\langle F \rangle \neq 0$, for example on the hidden brane, the auxiliary field component also obtains a non-zero VEV, with

$$\langle F_\phi \rangle \sim \frac{\langle F \rangle}{M_\text{P}} \sim m^{3/2}. \quad (6.65)$$

The non-dynamical conformal compensator field $\phi$ is taken to be dimensionless, so that $F_\phi$ has dimensions of [mass].

In the classical limit, there is still no supersymmetry breaking in the MSSM sector, due to the exponential suppression provided by the extra dimensions.$^\dagger$ However, there is an anomalous violation of superconformal (scale) invariance manifested in the running of the couplings. This causes supersymmetry breaking to show up in the MSSM by virtue of the non-zero beta functions and anomalous dimensions of the MSSM brane couplings and fields. The resulting soft terms are \[149\] (using $F_\phi$ to denote its VEV from now on):

$$M_a = F_\phi \beta g_a / g_a, \quad \langle m^2 \rangle^i_j = \frac{1}{2} |F_\phi|^2 \frac{d}{dt} \gamma^i_j = \frac{1}{2} |F_\phi|^2 \left[ \beta g_a \frac{\partial \gamma^i_j}{\partial g_a} + \left( \beta y^{kmm} \frac{\partial \gamma^i_j}{\partial y^{kmm}} + \text{c.c.} \right) \right], \quad \partial^{ijk} = -F_\phi \beta g_{ijk}, \quad (6.66, 6.67, 6.68)$$

where the anomalous dimensions $\gamma^i_j$ are normalized as in eqs. \[5.26\] and \[5.37\]-\[5.43\]. As in the GMSB scenario of the previous subsection, gaugino masses arise at one-loop order, but scalar squared masses

$^\dagger$AMSB can also be realized without invoking extra dimensions. The suppression of flavor-violating MSSM soft terms can instead be achieved using a strongly-coupled conformal field theory near an infrared-stable fixed point \[150\].
arise at two-loop order. Also, these results are approximately flavor-blind for the first two families, because the non-trivial flavor structure derives only from the MSSM Yukawa couplings.

There are several unique features of the AMSB scenario. First, there is no need to specify at which renormalization scale eqs. (6.66)-(6.68) should be applied as boundary conditions. This is because they hold at every renormalization scale, exactly, to all orders in perturbation theory. In other words, eqs. (6.66)-(6.68) are not just boundary conditions for the renormalization group equations of the soft parameters, but solutions as well. (These AMSB renormalization group trajectories can also be found from this renormalization group invariance property alone, without reference to the supergravity derivation.) In fact, even if there are heavy supermultiplets in the theory that have to be decoupled, the boundary conditions hold both above and below the arbitrary decoupling scale. This remarkable insensitivity to ultraviolet physics in AMSB ensures the absence of flavor violation in the low-energy MSSM soft terms. Another interesting prediction is that the gravitino mass $m_{3/2}$ in these models is actually much larger than the scale $m_{\text{soft}}$ of the MSSM soft terms, since the latter are loop-suppressed compared to eq. (6.65).

There is only one unknown parameter, $F_\phi$, among the MSSM soft terms in AMSB. Unfortunately, this exemplary falsifiability is marred by the fact that it is already falsified. The dominant contributions to the first-family squark and slepton squared masses are:

$$m_{\tilde{q}}^2 = \frac{|F_\phi|^2}{(16\pi^2)^2} \left( 8g_2^4 + \ldots \right), \quad (6.69)$$
$$m_{\tilde{\ell}_L}^2 = -\frac{|F_\phi|^2}{(16\pi^2)^2} \left( 3g_2^4 + \frac{99}{50}g_1^4 \right), \quad (6.70)$$
$$m_{\tilde{\ell}_R}^2 = -\frac{|F_\phi|^2}{(16\pi^2)^2} \frac{198}{25}g_1^4 \quad (6.71)$$

The squarks have large positive squared masses, but the sleptons have negative squared masses, so the AMSB model in its simplest form is not viable. These signs come directly from those of the beta functions of the strong and electroweak gauge interactions, as can be seen from the right side of eq. (6.67).

The characteristic ultraviolet insensitivity to physics at high mass scales also makes it somewhat non-trivial to modify the theory to escape this tachyonic slepton problem by deviating from the AMSB trajectory. There can be large deviations from AMSB provided by supergravity, but then in general the flavor-blindness is also forfeit. One way to modify AMSB is to introduce additional supermultiplets that contain supersymmetry-breaking mass splittings that are large compared to their average mass. Another way is to combine AMSB with gaugino mediation. Some other proposals can be found in [155]. Finally, there is a popular, if perhaps somewhat less motivated, approach in which a common parameter $m_0^2$ is added to all of the scalar squared masses at some scale, and chosen large enough to allow the sleptons to have positive squared masses above LEP bounds. This allows the phenomenology to be studied in a framework conveniently parameterized by just:

$$F_\phi, m_0^2, \tan \beta, \arg(\mu), \quad (6.72)$$

with $|\mu|$ and $b$ determined by requiring correct electroweak symmetry breaking as described in the next section. (Some sources use $m_{3/2}$ or $M_{\text{aux}}$ to denote $F_\phi$.) The MSSM gaugino masses at the leading non-trivial order are unaffected by the ad hoc addition of $m_0^2$:

$$M_1 = \frac{F_\phi}{16\pi^2} \frac{33}{5}g_1^2 \quad (6.73)$$
$$M_2 = \frac{F_\phi}{16\pi^2} g_2^2 \quad (6.74)$$
$$M_3 = -\frac{F_\phi}{16\pi^2} 3g_3^2 \quad (6.75)$$
This implies that $|M_2| \ll |M_1| \ll |M_3|$, so the lightest neutralino is actually mostly wino, with a lightest chargino that is only of order 200 MeV heavier, depending on the values of $\mu$ and $\tan \beta$. The decay $\tilde{C}_1^\pm \to \tilde{N}_1 \pi^\pm$ produces a very soft pion, implying unique and difficult signatures in colliders \cite{150-160}.

Another large general class of models breaks supersymmetry using the geometric or topological properties of the extra dimensions. In the Scherk-Schwarz mechanism \cite{161}, the symmetry is broken by assuming different boundary conditions for the fermion and boson fields on the compactified space. In supersymmetric models where the size of the extra dimension is parameterized by a modulus (a massless or nearly massless excitation) called a radion, the F-term component of the radion chiral supermultiplet can obtain a VEV, which becomes a source for supersymmetry breaking in the MSSM. These two ideas turn out to be often related. Some of the variety of models proposed along these lines can be found in \cite{162}. These mechanisms can also be combined with gaugino-mediation and AMSB. It seems likely that the possibilities are not yet fully explored.

7 The mass spectrum of the MSSM

7.1 Electroweak symmetry breaking and the Higgs bosons

In the MSSM, the description of electroweak symmetry breaking is slightly complicated by the fact that there are two complex Higgs doublets $H_u = (H_u^+, H_u^0)$ and $H_d = (H_d^0, H_d^-)$ rather than just one in the ordinary Standard Model. The classical scalar potential for the Higgs scalar fields in the MSSM is given by

$$V = (|\mu|^2 + m_{H_u}^2)(|H_u^0|^2 + |H_u^+|^2) + (|\mu|^2 + m_{H_d}^2)(|H_d^0|^2 + |H_d^-|^2)$$

$$+ b (H_u^+ H_d^- - H_d^0 H_u^0) + \text{c.c.}$$

$$- \frac{1}{8}(g^2 + g'^2)(|H_u^0|^2 + |H_u^+|^2 - |H_d^0|^2 - |H_d^-|^2)^2 + \frac{1}{2}g^2|H_u^+ H_d^- + H_u^0 H_d^0|^2.$$  \hspace{1cm} (7.1)

The terms proportional to $|\mu|^2$ come from F-terms [see eq. \ref{5.5}]. The terms proportional to $g^2$ and $g'^2$ are the D-term contributions, obtained from the general formula eq. \ref{5.7} after some rearranging. Finally, the terms proportional to $m_{H_u}^2$, $m_{H_d}^2$ and $b$ are just a rewriting of the last three terms of eq. \ref{5.12}. The full scalar potential of the theory also includes many terms involving the squark and slepton fields that we can ignore here, since they do not get VEVs because they have large positive squared masses.

We now have to demand that the minimum of this potential should break electroweak symmetry down to electromagnetism $SU(2)_L \times U(1)_Y \to U(1)_{\text{EM}}$, in accord with experiment. We can use the freedom to make gauge transformations to simplify this analysis. First, the freedom to make $SU(2)_L$ gauge transformations allows us to rotate away a possible VEV for one of the weak isospin components of one of the scalar fields, so without loss of generality we can take $H_u^+ = 0$ at the minimum of the potential. Then one finds that a minimum of the potential satisfying $\partial V / \partial H_u^+ = 0$ must also have $H_d^- = 0$. This is good, because it means that at the minimum of the potential electromagnetism is necessarily unbroken, since the charged components of the Higgs scalars cannot get VEVs. After setting $H_u^+ = H_d^- = 0$, we are left to consider the scalar potential

$$V = (|\mu|^2 + m_{H_u}^2)|H_u^0|^2 + (|\mu|^2 + m_{H_d}^2)|H_d^0|^2 - (b H_d^0 H_u^0 + \text{c.c.})$$

$$+ \frac{1}{8}(g^2 + g'^2)(|H_u^0|^2 - |H_d^0|^2)^2.$$  \hspace{1cm} (7.2)

The only term in this potential that depends on the phases of the fields is the $b$-term. Therefore, a redefinition of the phase of $H_u$ or $H_d$ can absorb any phase in $b$, so we can take $b$ to be real and positive.
Then it is clear that a minimum of the potential $V$ requires that $H_u^0 H_d^0$ is also real and positive, so $\langle H_u^0 \rangle$ and $\langle H_d^0 \rangle$ must have opposite phases. We can therefore use a $U(1)_Y$ gauge transformation to make them both be real and positive without loss of generality, since $H_u$ and $H_d$ have opposite weak hypercharges ($\pm 1/2$). It follows that CP cannot be spontaneously broken by the Higgs scalar potential, since the VEVs and $b$ can be simultaneously chosen real, as a convention. This means that the Higgs scalar mass eigenstates can be assigned well-defined eigenvalues of CP, at least at tree-level. (CP-violating phases in other couplings can induce loop-suppressed CP violation in the Higgs sector, but do not change the fact that $b$, $\langle H_u^0 \rangle$, and $\langle H_d^0 \rangle$ can always be chosen real and positive.)

In order for the MSSM scalar potential to be viable, we must first make sure that the potential is bounded from below for arbitrarily large values of the scalar fields, so that $V$ will really have a minimum. (Recall from the discussion in sections 3.2 and 3.4 that scalar potentials in purely supersymmetric theories are automatically non-negative and so clearly bounded from below. But, now that we have introduced supersymmetry breaking, we must be careful.) The scalar quartic interactions in $V$ will stabilize the potential for almost all arbitrarily large values of $H_u^0$ and $H_d^0$. However, for the special directions in field space $|H_u^0| = |H_d^0|$, the quartic contributions to $V$ [the second line in eq. (7.2)] are identically zero. Such directions in field space are called $D$-flat directions, because along them the part of the scalar potential coming from $D$-terms vanishes. In order for the potential to be bounded from below, we need the quadratic part of the scalar potential to be positive along the $D$-flat directions. This requirement amounts to

$$2b < 2|\mu|^2 + m_{H_u}^2 + m_{H_d}^2.$$

(7.3)

Note that the $b$-term always favors electroweak symmetry breaking. Requiring that one linear combination of $H_u^0$ and $H_d^0$ has a negative squared mass near $H_u^0 = H_d^0 = 0$ gives

$$b^2 > (|\mu|^2 + m_{H_u}^2)(|\mu|^2 + m_{H_d}^2).$$

(7.4)

If this inequality is not satisfied, then $H_u^0 = H_d^0 = 0$ will be a stable minimum of the potential (or there will be no stable minimum at all), and electroweak symmetry breaking will not occur.

Interestingly, if $m_{H_u}^2 = m_{H_d}^2$ then the constraints eqs. (7.3) and (7.4) cannot both be satisfied. In models derived from the minimal supergravity or gauge-mediated boundary conditions, $m_{H_u}^2 = m_{H_d}^2$ is supposed to hold at tree level at the input scale, but the $X_t$ contribution to the RG equation for $m_{H_u}^2$ [eq. (5.01)] naturally pushes it to negative or small values $m_{H_u}^2 < m_{H_d}^2$ at the electroweak scale. Unless this effect is significant, the parameter space in which the electroweak symmetry is broken would be quite small. So in these models electroweak symmetry breaking is actually driven by quantum corrections; this mechanism is therefore known as radiative electroweak symmetry breaking. Note that although a negative value for $|\mu|^2 + m_{H_u}^2$ will help eq. (7.3) to be satisfied, it is not strictly necessary. Furthermore, even if $m_{H_u}^2 < 0$, there may be no electroweak symmetry breaking if $|\mu|$ is too large or if $b$ is too small. Still, the large negative contributions to $m_{H_u}^2$ from the RG equation are an important factor in ensuring that electroweak symmetry breaking can occur in models with simple boundary conditions for the soft terms. The realization that this works most naturally with a large top-quark Yukawa coupling provides additional motivation for these models [163, 134].

Having established the conditions necessary for $H_u^0$ and $H_d^0$ to get non-zero VEVs, we can now require that they are compatible with the observed phenomenology of electroweak symmetry breaking, $SU(2)_L \times U(1)_Y \rightarrow U(1)_{EM}$. Let us write

$$v_u = \langle H_u^0 \rangle, \quad v_d = \langle H_d^0 \rangle.$$

(7.5)

These VEVs are related to the known mass of the $Z^0$ boson and the electroweak gauge couplings:

$$v_u^2 + v_d^2 = v^2 = 2m_Z^2/(g^2 + g'^2) \approx (174 \text{ GeV})^2.$$

(7.6)
The ratio of the VEVs is traditionally written as

$$\tan \beta \equiv \frac{v_u}{v_d}. \quad (7.7)$$

The value of $\tan \beta$ is not fixed by present experiments, but it depends on the Lagrangian parameters of the MSSM in a calculable way. Since $v_u = v \sin \beta$ and $v_d = v \cos \beta$ were taken to be real and positive by convention, we have $0 < \beta < \pi/2$, a requirement that will be sharpened below. Now one can write down the conditions $\partial V/\partial H_u^0 = \partial V/\partial H_d^0 = 0$ under which the potential eq. (7.2) will have a minimum satisfying eqs. (7.6) and (7.7):

$$m_{H_u}^2 + |\mu|^2 - b \cot \beta - (m_Z^2/2) \cos(2\beta) = 0, \quad (7.8)$$
$$m_{H_d}^2 + |\mu|^2 - b \tan \beta + (m_Z^2/2) \cos(2\beta) = 0. \quad (7.9)$$

It is easy to check that these equations indeed satisfy the necessary conditions eqs. (7.3) and (7.4). They allow us to eliminate two of the Lagrangian parameters $b$ and $|\mu|$ in favor of $\tan \beta$, but do not determine the phase of $\mu$. Taking $|\mu|^2$, $b$, $m_{H_u}^2$, and $m_{H_d}^2$ as input parameters, and $m_Z^2$ and $\tan \beta$ as output parameters obtained by solving these two equations, one obtains:

$$\sin(2\beta) = \frac{2b}{m_{H_u}^2 + m_{H_d}^2 + 2|\mu|^2}, \quad (7.10)$$
$$m_Z^2 = \frac{(m_{H_d}^2 - m_{H_u}^2)}{\sqrt{1 - \sin^2(2\beta)}} - m_{H_u}^2 - m_{H_d}^2 - 2|\mu|^2. \quad (7.11)$$

(Note that $\sin(2\beta)$ is always positive. If $m_{H_u}^2 < m_{H_d}^2$, as is usually assumed, then $\cos(2\beta)$ is negative; otherwise it is positive.)

As an aside, eqs. (7.10) and (7.11) highlight the “$\mu$ problem” already mentioned in section 5.1. Without miraculous cancellations, all of the input parameters ought to be within an order of magnitude or two of $m_Z^2$. However, in the MSSM, $\mu$ is a supersymmetry-respecting parameter appearing in the superpotential, while $b$, $m_{H_u}^2$, $m_{H_d}^2$ are supersymmetry-breaking parameters. This has lead to a widespread belief that the MSSM must be extended at very high energies to include a mechanism that relates the effective value of $\mu$ to the supersymmetry-breaking mechanism in some way; see section 10.2 and refs. [57]-[59] for examples.

Even if the value of $\mu$ is set by soft supersymmetry breaking, the cancellation needed by eq. (7.11) is often remarkable when evaluated in specific model frameworks, after constraints from direct searches for the Higgs bosons and superpartners are taken into account. For example, expanding for large $\tan \beta$, eq. (7.11) becomes

$$m_Z^2 = -2(m_{H_u}^2 + |\mu|^2) + \frac{2}{\tan^2 \beta}(m_{H_d}^2 - m_{H_u}^2) + O(1/\tan^4 \beta). \quad (7.12)$$

Typical viable solutions for the MSSM have $-m_{H_u}^2$ and $|\mu|^2$ each much larger than $m_Z^2$, so that significant cancellation is needed. In particular, large top squark squared masses, needed to avoid having the Higgs boson mass turn out too small [see eq. (7.25) below] compared to the direct search limits from LEP, will feed into $m_{H_u}^2$. The cancellation needed in the minimal model may therefore be at the several per cent level. It is impossible to objectively characterize whether this should be considered worrisome, but it could be taken as a weak hint in favor of non-minimal models.

The discussion above is based on the tree-level potential, and involves running renormalized Lagrangian parameters, which depend on the choice of renormalization scale. In practice, one must include radiative corrections at one-loop order, at least, in order to get numerically stable results. To do this, one can compute the loop corrections $\Delta V$ to the effective potential $V_{\text{eff}}(v_u, v_d) = V + \Delta V$ as a
function of the VEVs. The impact of this is that the equations governing the VEVs of the full effective potential are obtained by simply replacing

\[ m_{H_u}^2 \rightarrow m_{H_u}^2 + \frac{1}{2v_u} \frac{\partial (\Delta V)}{\partial v_u}, \quad m_{H_d}^2 \rightarrow m_{H_d}^2 + \frac{1}{2v_d} \frac{\partial (\Delta V)}{\partial v_d} \]  

(7.13)
in eqs. (7.11), treating \( v_u \) and \( v_d \) as real variables in the differentiation. The result for \( \Delta V \) has now been obtained through two-loop order in the MSSM [163]. The most important corrections come from the one-loop diagrams involving the top squarks and top quark, and experience shows that the validity of the tree-level approximation and the convergence of perturbation theory are therefore improved by choosing a renormalization scale roughly of order the average of the top squark masses.

The Higgs scalar fields in the MSSM consist of two complex \( SU(2)_L \)-doublet, or eight real, scalar degrees of freedom. When the electroweak symmetry is broken, three of them are the would-be Nambu-Goldstone bosons \( G^0, G^\pm \), which become the longitudinal modes of the \( Z^0 \) and \( W^\pm \) massive vector bosons. The remaining five Higgs scalar mass eigenstates consist of two CP-even neutral scalars \( h^0 \) and \( H^0 \), one CP-odd neutral scalar \( A^0 \), and a charge +1 scalar \( H^+ \) and its conjugate charge −1 scalar \( H^- \). (Here we define \( G^- = G^{++} \) and \( H^- = H^{++} \).) The gauge-eigenstate fields can be expressed in terms of the mass eigenstate fields as:

\[
\begin{pmatrix}
H_u^0 \\
H_d^0
\end{pmatrix} = \begin{pmatrix} v_u + i R_\alpha \beta_0 A^0 \beta_0 \\
v_d + i R_\alpha \beta_0 A^0 \beta_0
\end{pmatrix} \quad \text{and} \quad \begin{pmatrix}
H_u^\pm \\
H_d^\pm
\end{pmatrix} = \begin{pmatrix} R_\beta & (\sin \beta_0 & \cos \beta_0) \\
(\cos \beta_0 & \sin \beta_0)
\end{pmatrix} \begin{pmatrix} G^0 \\
A^0
\end{pmatrix}
\]

(7.14-7.15)

where the orthogonal rotation matrices

\[
R_\alpha = \begin{pmatrix} \cos \alpha & \sin \alpha \\
-\sin \alpha & \cos \alpha
\end{pmatrix}, \quad R_\beta = \begin{pmatrix} \sin \beta_0 & \cos \beta_0 \\
-\cos \beta_0 & \sin \beta_0
\end{pmatrix}
\]

(7.16-7.17)

are chosen so that the quadratic part of the potential has diagonal squared-masses:

\[
V = \frac{1}{2} m_{h^0}^2 (h^0)^2 + \frac{1}{2} m_{H^0}^2 (H^0)^2 + \frac{1}{2} m_{A^0}^2 (A^0)^2 + \frac{1}{2} m_{G^0}^2 (G^0)^2 + \frac{1}{2} m_{G^\pm}^2 (G^\pm)^2 + \frac{1}{2} m_{H^\pm}^2 (H^\pm)^2 + \ldots
\]

(7.18)

Then, provided that \( v_u, v_d \) minimize the tree-level potential, one finds that \( \beta_0 = \beta_\pm = \beta \), and \( m_{G^0}^2 = m_{G^\pm}^2 = 0 \), and

\[
\begin{align*}
m_{h^0}^2 &= 2b/\sin(2\beta) = 2|\mu|^2 + m_{H_u}^2 + m_{H_d}^2 \\
m_{h^0, H^0}^2 &= \frac{1}{2} \left( m_{A^0}^2 + m_Z^2 + \sqrt{(m_{A^0}^2 - m_Z^2)^2 + 4m_Z^2 m_{A^0}^2 \sin^2(2\beta)} \right), \\
m_{H^\pm}^2 &= m_{A^0}^2 + m_Z^2.
\end{align*}
\]

(7.19-7.21)

The mixing angle \( \alpha \) is determined, at tree-level, by

\[
\frac{\sin 2\alpha}{\sin 2\beta} = -\frac{m_{H^0}^2 + m_{A^0}^2}{m_{H^0}^2 - m_{A^0}^2}, \quad \frac{\tan 2\alpha}{\tan 2\beta} = \frac{m_{A^0}^2 + m_Z^2}{m_{A^0}^2 - m_Z^2},
\]

(7.22)

\footnote{It is often more useful to expand around VEVs \( v_u, v_d \) that do not minimize the tree-level potential, for example to minimize the loop-corrected effective potential instead. In that case, \( \beta, \beta_0, \) and \( \beta_\pm \) are all slightly different.}
Figure 7.1: A contour map of the Higgs potential, for a typical case with $\tan \beta \approx -\cot \alpha \approx 10$. The minimum of the potential is marked by $+$, and the contours are equally spaced equipotentials. Oscillations along the shallow direction, with $H_u^0/H_d^0 \approx 10$, correspond to the mass eigenstate $h^0$, while the orthogonal steeper direction corresponds to the mass eigenstate $H^0$.

\[
\Delta(m_{h^0}^2) = h^0 - \frac{t}{2} - h^0 - \tilde{t} + h^0 - \tilde{t}
\]

Figure 7.2: Contributions to the MSSM lightest Higgs mass from top-quark and top-squark one-loop diagrams. Incomplete cancellation, due to soft supersymmetry breaking, leads to a large positive correction to $m_{h^0}^2$ in the limit of heavy top squarks.

and is traditionally chosen to be negative; it follows that $-\pi/2 < \alpha < 0$ (provided $m_{A^0} > m_Z$). The Feynman rules for couplings of the mass eigenstate Higgs scalars to the Standard Model quarks and leptons and the electroweak vector bosons, as well as to the various sparticles, have been worked out in detail in ref. [165, 166].

The masses of $A^0$, $H^0$ and $H^\pm$ can in principle be arbitrarily large since they all grow with $b/\sin(2\beta)$. In contrast, the mass of $h^0$ is bounded above. From eq. (7.20), one finds at tree-level [167]:

\[
m_{h^0} < m_Z|\cos(2\beta)|
\]  

This corresponds to a shallow direction in the scalar potential, along the direction $(H_u^0 - v_u, H_d^0 - v_d) \propto (\cos \alpha, -\sin \alpha)$. The existence of this shallow direction can be traced to the fact that the quartic Higgs couplings are given by the square of the electroweak gauge couplings, via the $D$-term. A contour map of the potential, for a typical case with $\tan \beta \approx -\cot \alpha \approx 10$, is shown in figure 7.1. If the tree-level inequality (7.23) were robust, the lightest Higgs boson of the MSSM would have been discovered at LEP2. However, the tree-level formula for the squared mass of $h^0$ is subject to quantum corrections that are relatively drastic. The largest such contributions typically come from top and stop loops, as shown\footnote{In general, one-loop 1-particle-reducible tadpole diagrams should also be included. However, they just cancel against tree-level tadpoles, and so both can be omitted, if the VEVs $v_u$ and $v_d$ are taken at the minimum of the loop-corrected effective potential (see previous footnote).} in fig. 7.2. In the simple limit of top squarks that have a small mixing in the gauge eigenstate basis and with masses $m_{\tilde{t}_1}$, $m_{\tilde{t}_2}$ much greater than the top quark mass $m_t$, one finds a large positive one-loop radiative correction to eq. (7.20):

\[
\Delta(m_{h^0}^2) = \frac{3}{4\pi^2} \cos^2 \alpha \, y_t^2 m_t^2 \ln \left( \frac{m_{\tilde{t}_1} m_{\tilde{t}_2}}{m_t^2} \right).
\]  

This shows that $m_{h^0}$ can exceed the LEP bounds.
Figure 7.3: Integrating out the top quark and top squarks yields large positive contributions to the quartic Higgs coupling in the low-energy effective theory, especially from these one-loop diagrams.

An alternative way to understand the size of the radiative correction to the $h^0$ mass is to consider an effective theory in which the heavy top squarks and top quark have been integrated out. The quartic Higgs couplings in the low-energy effective theory get large positive contributions from the the one-loop diagrams of fig. 7.3. This increases the steepness of the Higgs potential, and can be used to obtain the same result for the enhanced $h^0$ mass.

An interesting case, often referred to as the “decoupling limit”, occurs when $m_{A^0} \gg m_Z$. Then $m_{h^0}$ can saturate the upper bounds just mentioned, with $m_{h^0}^2 \approx m_Z^2 \cos^2(2\beta) +$ loop corrections. The particles $A^0$, $H^0$, and $H^\pm$ will be much heavier and nearly degenerate, forming an isospin doublet that decouples from sufficiently low-energy experiments. The angle $\alpha$ is very nearly $\beta - \pi/2$, and $h^0$ has the same couplings to quarks and leptons and electroweak gauge bosons as would the physical Higgs boson of the ordinary Standard Model without supersymmetry. Indeed, model-building experiences have shown that it is not uncommon for $h^0$ to behave in a way nearly indistinguishable from a Standard Model-like Higgs boson, even if $m_{A^0}$ is not too huge. However, it should be kept in mind that the couplings of $h^0$ might turn out to deviate significantly from those of a Standard Model Higgs boson.

Top-squark mixing (to be discussed in section 7.4) can result in a further large positive contribution to $m_{h^0}^2$. At one-loop order, and working in the decoupling limit for simplicity, eq. (7.24) generalizes to:

$$m_{h^0}^2 = m_Z^2 \cos^2(2\beta) + \frac{3}{4\pi^2} \sin^2(\beta) \frac{y_t^2}{y_1} \left[ m_t^2 \ln \left( \frac{m_t}{m_{t_1}} \right) + c_t^2 s_t^2 (m_{t_2} - m_{t_1}) \ln \left( \frac{m_{t_2}}{m_{t_1}} \right) + c_t^4 s_t^4 \left( \frac{m_{t_2}^2 - m_{t_1}^2}{2} \right) \ln \left( \frac{m_{t_2}^2}{m_{t_1}^2} \right) \right].$$

(7.25)

Here $c_t$ and $s_t$ are the cosine and sine of a top squark mixing angle $\theta_t$, defined more specifically below following eq. (7.7). For fixed top-squark masses, the maximum possible $h^0$ mass occurs for rather large top squark mixing, $c_t^2 s_t^2 = m_t^2 / \left[ m_{t_2}^2 + m_{t_1}^2 - 2(m_{t_2} - m_{t_1}) / \ln (m_{t_2}^2 / m_{t_1}^2) \right]$ or 1/4, whichever is less. It follows that the quantity in square brackets in eq. (7.25) is always less than $m_t^2 \ln (m_{t_2}^2 / m_{t_1}^2) + 3$. The LEP constraints on the MSSM Higgs sector make the case of large top-squark mixing noteworthy.

Including these and other important corrections [168, 177], one can obtain only a weaker, but still very interesting, bound

$$m_{h^0} \lesssim 135 \text{ GeV}$$

(7.26)

in the MSSM. This assumes that all of the sparticles that can contribute to $m_{h^0}^2$ in loops have masses that do not exceed 1 TeV. By adding extra supermultiplets to the MSSM, this bound can be made even weaker. However, assuming that none of the MSSM sparticles have masses exceeding 1 TeV and that all of the couplings in the theory remain perturbative up to the unification scale, one still has [178]

$$m_{h^0} \lesssim 150 \text{ GeV}.$$  

(7.27)

This bound is also weakened if, for example, the top squarks are heavier than 1 TeV, but the upper bound rises only logarithmically with the soft masses, as can be seen from eq. (7.24). Thus it is a fairly robust prediction of supersymmetry at the electroweak scale that at least one of the Higgs scalar bosons must be light. (However, if one is willing to extend the MSSM in a completely general way above the
electroweak scale, none of these bounds need apply.) For a given set of model parameters, it is always important to take into account the complete set of one-loop corrections and even the dominant two-loop effects in order to get reasonably accurate predictions for the Higgs masses and mixings [168]-[177].

In the MSSM, the masses and CKM mixing angles of the quarks and leptons are determined not only by the Yukawa couplings of the superpotential but also the parameter \( \tan \beta \). This is because the top, charm and up quark mass matrix is proportional to \( v_u = v \sin \beta \) and the bottom, strange, and down quarks and the charge leptons get masses proportional to \( v_d = v \cos \beta \). At tree-level,

\[
m_t = y_t v \sin \beta, \quad m_b = y_b v \cos \beta, \quad m_\tau = y_\tau v \cos \beta.
\] (7.28)

These relations hold for the running masses rather than the physical pole masses, which are significantly larger for \( t, b \) [179]. Including those corrections, one can relate the Yukawa couplings to \( \tan \beta \) and the known fermion masses and CKM mixing angles. It is now clear why we have not neglected \( y_b \) and \( y_\tau \), even though \( m_b, m_\tau \ll m_t \). To a first approximation, \( y_b/y_t = (m_b/m_t) \tan \beta \) and \( y_\tau/y_t = (m_\tau/m_t) \tan \beta \), so that \( y_b \) and \( y_\tau \) cannot be neglected if \( \tan \beta \) is much larger than 1. In fact, there are good theoretical motivations for considering models with large \( \tan \beta \). For example, models based on the GUT gauge group \( SO(10) \) can unify the running top, bottom and tau Yukawa couplings at the unification scale; this requires \( \tan \beta \) to be very roughly of order \( m_t/m_b \) [180] [181].

Note that if one tries to make \( \sin \beta \) too small, \( y_t \) will be nonperturbatively large. Requiring that \( y_t \) does not blow up above the electroweak scale, one finds that \( \tan \beta \gtrsim 1.2 \) or so, depending on the mass of the top quark, the QCD coupling, and other details. In principle, there is also a constraint on \( \cos \beta \) if one requires that \( y_b \) and \( y_\tau \) do not become nonperturbatively large. This gives a rough upper bound of \( \tan \beta \lesssim 65 \). However, this is complicated somewhat by the fact that the bottom quark mass gets significant one-loop non-QCD corrections in the large \( \tan \beta \) limit [181]. One can obtain a stronger upper bound on \( \tan \beta \) in some models where \( m_{\tilde{H}_u}^2 = m_{\tilde{H}_d}^2 \) at the input scale, by requiring that \( y_b \) does not significantly exceed \( y_t \). [Otherwise, \( X_b \) would be larger than \( X_t \) in eqs. (5.61) and (5.62), so one would expect \( m_{\tilde{H}_d}^2 < m_{\tilde{H}_u}^2 \) at the electroweak scale, and the minimum of the potential would have \( \langle H_d^0 \rangle > \langle H_u^0 \rangle \). This would be a contradiction with the supposition that \( \tan \beta \) is large.] The parameter \( \tan \beta \) also directly impacts the masses and mixings of the MSSM particles, as we will see below.

### 7.2 Neutralinos and charginos

The higgsinos and electroweak gauginos mix with each other because of the effects of electroweak symmetry breaking. The neutral higgsinos (\( \tilde{H}_u^- \) and \( \tilde{H}_d^- \)) and the neutral gauginos (\( \tilde{B}, \tilde{W}^0 \)) combine to form four mass eigenstates called *neutralinos*. The charged higgsinos (\( \tilde{H}_u^+ \) and \( \tilde{H}_d^- \)) and winos (\( \tilde{W}^+ \) and \( \tilde{W}^- \)) mix to form two mass eigenstates with charge \( \pm 1 \) called *charginos*. We will denote\(^1\) the neutralino and chargino mass eigenstates by \( \tilde{N}_i \) (\( i = 1, 2, 3, 4 \)) and \( \tilde{C}_i^\pm \) (\( i = 1, 2 \)). By convention, these are labeled in ascending order, so that \( m_{\tilde{N}_1} < m_{\tilde{N}_2} < m_{\tilde{N}_3} < m_{\tilde{N}_4} \) and \( m_{\tilde{C}_1} < m_{\tilde{C}_2} \). The lightest neutralino, \( \tilde{N}_1 \), is usually assumed to be the LSP, unless there is a lighter gravitino or unless \( R \)-parity is not conserved, because it is the only MSSM particle that can make a good dark matter candidate. In this subsection, we will describe the mass spectrum and mixing of the neutralinos and charginos in the MSSM.

In the gauge-eigenstate basis \( \psi^0 = (\tilde{B}, \tilde{W}^0, \tilde{H}_d^0, \tilde{H}_u^0) \), the neutralino mass part of the Lagrangian is

\[
\mathcal{L}_{\text{neutralino mass}} = -\frac{1}{2} (\psi^0)^T M_\chi \psi^0 + \text{c.c.},
\] (7.29)

\(^1\)Other common notations use \( \tilde{\chi}^0_i \) or \( \tilde{Z}_i \) for neutralinos, and \( \tilde{\chi}^\pm_i \) or \( \tilde{W}^\pm_i \) for charginos.
where

$$
M_N = \begin{pmatrix}
M_1 & 0 & -g'd_d/\sqrt{2} & g'u_u/\sqrt{2} \\
0 & M_2 & g'd_d/\sqrt{2} & -g'u_u/\sqrt{2} \\
-g'd_d/\sqrt{2} & g'd_d/\sqrt{2} & 0 & -\mu \\
g'u_u/\sqrt{2} & -g'u_u/\sqrt{2} & -\mu & 0
\end{pmatrix}.
$$

(7.30)

The entries $M_1$ and $M_2$ in this matrix come directly from the MSSM soft Lagrangian [see eq. (5.12)], while the entries $-\mu$ are the supersymmetric higgsino mass terms [see eq. (5.1)]. The terms proportional to $g,g'$ are the result of Higgs-higgsino-gaugino couplings [see eq. (3.72) and Figure 3.3g,h], with the Higgs scalars replaced by their VEVs [eqs. (7.6), (7.7)]. This can also be written as

$$
\tilde{M}_N = \begin{pmatrix}
M_1 & 0 & -c_\beta s_W m_Z & s_\beta s_W m_Z \\
0 & M_2 & c_\beta c_W m_Z & -s_\beta c_W m_Z \\
-c_\beta s_W m_Z & c_\beta c_W m_Z & 0 & -\mu \\
c_\beta s_W m_Z & -s_\beta c_W m_Z & -\mu & 0
\end{pmatrix}.
$$

(7.31)

Here we have introduced abbreviations $s_\beta = \sin \beta$, $c_\beta = \cos \beta$, $s_W = \sin \theta_W$, and $c_W = \cos \theta_W$. The mass matrix $\tilde{M}_N$ can be diagonalized by a unitary matrix $N$ to obtain mass eigenstates:

$$
\bar{N}_i = N_{ij} \psi^0_j,
$$

(7.32)

so that

$$
N^* M_N N^{-1} = \begin{pmatrix}
m_{\bar{N}_1} & 0 & 0 & 0 \\
0 & m_{\bar{N}_2} & 0 & 0 \\
0 & 0 & m_{\bar{N}_3} & 0 \\
0 & 0 & 0 & m_{\bar{N}_4}
\end{pmatrix}
$$

(7.33)

has real positive entries on the diagonal. These are the magnitudes of the eigenvalues of $M_N$, or equivalently the square roots of the eigenvalues of $M_N^T M_N$. The indices $(i,j)$ on $N_{ij}$ are (mass, gauge) eigenstate labels. The mass eigenvalues and the mixing matrix $N_{ij}$ can be given in closed form in terms of the parameters $M_1, M_2, \mu$ and $\tan \beta$, by solving quartic equations, but the results are very complicated and not illuminating.

In general, the parameters $M_1, M_2$, and $\mu$ in the equations above can have arbitrary complex phases. A redefinition of the phases of $B$ and $W$ always allows us to choose a convention in which $M_1$ and $M_2$ are both real and positive. The phase of $\mu$ within that convention is then really a physical parameter and cannot be rotated away. [We have already used up the freedom to redefine the phases of the Higgs fields, since we have picked $b$ and $\langle H^0_u \rangle$ and $\langle H^0_d \rangle$ to be real and positive, to guarantee that the off-diagonal entries in eq. (7.31) proportional to $m_Z$ are real.] However, if $\mu$ is not real, then there can be potentially disastrous CP-violating effects in low-energy physics, including electric dipole moments for both the electron and the neutron. Therefore, it is usual [although not strictly mandatory, because of the possibility of nontrivial cancellations involving the phases of the (scalar) couplings and the gluino mass] to assume that $\mu$ is real in the same set of phase conventions that make $M_1, M_2, b,$ $\langle H^0_u \rangle$ and $\langle H^0_d \rangle$ real and positive. The sign of $\mu$ is still undetermined by this constraint.

In models that satisfy eq. (5.49), one has the nice prediction

$$
M_1 \approx \frac{5}{3} \tan^2 \theta_W M_2 \approx 0.5 M_2,
$$

(7.34)

at the electroweak scale. If so, then the neutralino masses and mixing angles depend on only three unknown parameters. This assumption is sufficiently theoretically compelling that it has been made...
in most phenomenological studies; nevertheless it should be recognized as an assumption, to be tested someday by experiment.

There is a not-unlikely limit in which electroweak symmetry breaking effects can be viewed as a small perturbation on the neutralino mass matrix. If

\[ m_Z < |\mu \pm M_1|, |\mu \pm M_2|, \]  

(7.35)

then the neutralino mass eigenstates are very nearly a “bino-like” \( \tilde{N}_1 \approx \tilde{B} \); a “wino-like” \( \tilde{N}_2 \approx \tilde{W}^0 \); and “higgsino-like” \( \tilde{N}_3, \tilde{N}_4 \approx (\tilde{H}_u^0 \pm \tilde{H}_d^0)/\sqrt{2} \), with mass eigenvalues:

\[
m_{\tilde{N}_1} = M_1 - \frac{m_Z^2 s_W^2 (M_1 + \mu \sin 2\beta)}{\mu^2 - M_1^2} + \ldots
\]

(7.36)

\[
m_{\tilde{N}_2} = M_2 - \frac{m_W^2 (M_2 + \mu \sin 2\beta)}{\mu^2 - M_2^2} + \ldots
\]

(7.37)

\[
m_{\tilde{N}_3}, m_{\tilde{N}_4} = |\mu| + \frac{m_Z^2 (I - \sin 2\beta)(\mu + M_1 c_W^2 + M_2 s_W^2)}{2(\mu + M_1)(\mu + M_2)} + \ldots,
\]

(7.38)

\[
m_{\tilde{N}_3}, m_{\tilde{N}_4} = |\mu| + \frac{m_Z^2 (I + \sin 2\beta)(\mu - M_1 c_W^2 - M_2 s_W^2)}{2(\mu - M_1)(\mu - M_2)} + \ldots
\]

(7.39)

where we have taken \( M_1 \) and \( M_2 \) real and positive by convention, and assumed \( \mu \) is real with sign \( I = \pm 1 \). The subscript labels of the mass eigenstates may need to be rearranged depending on the numerical values of the parameters; in particular the above labeling of \( \tilde{N}_1 \) and \( \tilde{N}_2 \) assumes \( M_1 < M_2 \ll |\mu| \). This limit, leading to a bino-like neutralino LSP, often emerges from minimal supergravity boundary conditions on the soft parameters, which tend to require it in order to get correct electroweak symmetry breaking.

The chargino spectrum can be analyzed in a similar way. In the gauge-eigenstate basis \( \psi^\pm = (\tilde{W}^+, \tilde{H}_u^+, \tilde{W}^-, \tilde{H}_d^-) \), the chargino mass terms in the Lagrangian are

\[ \mathcal{L}_{\text{chargino mass}} = -\frac{1}{2} (\psi^+)^T M_{\tilde{C}} \psi^+ + \text{c.c.} \]

(7.40)

where, in \( 2 \times 2 \) block form,

\[ M_{\tilde{C}} = \begin{pmatrix} 0 & X^T \\ X & 0 \end{pmatrix}, \]

(7.41)

with

\[ X = \begin{pmatrix} M_2 & g v_u \\ g v_d & \mu \end{pmatrix} = \begin{pmatrix} M_2 & \sqrt{2} c_\beta m_W \\ \sqrt{2} c_\beta m_W & \mu \end{pmatrix}. \]

(7.42)

The mass eigenstates are related to the gauge eigenstates by two unitary \( 2 \times 2 \) matrices \( U \) and \( V \) according to

\[
\begin{pmatrix} \tilde{C}^+_1 \\ \tilde{C}^-_2 \end{pmatrix} = V \begin{pmatrix} \tilde{W}^+ \\ \tilde{H}_u^+ \end{pmatrix}, \quad \begin{pmatrix} \tilde{C}^-_1 \\ \tilde{C}^-_2 \end{pmatrix} = U \begin{pmatrix} \tilde{W}^- \\ \tilde{H}_d^- \end{pmatrix}.
\]

(7.43)

Note that the mixing matrix for the positively charged left-handed fermions is different from that for the negatively charged left-handed fermions. They are chosen so that

\[ U^* X V^{-1} = \begin{pmatrix} m_{\tilde{C}_1} & 0 \\ 0 & m_{\tilde{C}_2} \end{pmatrix}, \]

(7.44)
with positive real entries $m_{\tilde{C}_i}$. Because these are only $2 \times 2$ matrices, it is not hard to solve for the masses explicitly:

$$m_{\tilde{C}_1}^2, m_{\tilde{C}_2}^2 = \frac{1}{2} \left[ |M_2|^2 + |\mu|^2 + 2m_W^2 \right] \mp \sqrt{\left( |M_2|^2 + |\mu|^2 + 2m_W^2 \right)^2 - 4|\mu M_2 - m_W^2 \sin 2\beta|^2 \right]. \quad (7.45)$$

These are the (doubly degenerate) eigenvalues of the $4 \times 4$ matrix $M^\dagger \tilde{C} M \tilde{C}$, or equivalently the eigenvalues of $X^\dagger X$, since

$$VX^\dagger X^{-1} = U^* XX^\dagger U^T = \begin{pmatrix} m_{\tilde{C}_1}^2 & 0 \\ 0 & m_{\tilde{C}_2}^2 \end{pmatrix}. \quad (7.46)$$

(But, they are not the squares of the eigenvalues of $X$.) In the limit of eq. (7.35) with real $M_2$ and $\mu$, the chargino mass eigenstates consist of a wino-like $\tilde{C}_1^\pm$ and a higgsino-like $\tilde{C}_2^\pm$, with masses

$$m_{\tilde{C}_1} = M_2 - \frac{m_W^2(M_2 + \mu \sin 2\beta)}{\mu^2 - M_2^2} + \ldots \quad (7.47)$$

$$m_{\tilde{C}_2} = |\mu| + \frac{m_W^2I(\mu + M_2 \sin 2\beta)}{\mu^2 - M_2^2} + \ldots \quad (7.48)$$

Here again the labeling assumes $M_2 < |\mu|$, and $I$ is the sign of $\mu$. Amusingly, $\tilde{C}_1$ is nearly degenerate with the neutralino $\tilde{N}_2$ in the approximation shown, but that is not an exact result. Their higgsino-like colleagues $\tilde{N}_3, \tilde{N}_4$ and $\tilde{C}_2$ have masses of order $|\mu|$. The case of $M_1 \approx 0, M_2 \ll |\mu|$ is not uncommonly found in viable models following from the boundary conditions in section 6, and it has been elevated to the status of a benchmark framework in many phenomenological studies. However it cannot be overemphasized that such expectations are not mandatory.

The Feynman rules involving neutralinos and charginos may be inferred in terms of $N, U$ and $V$ from the MSSM Lagrangian as discussed above; they are collected in refs. 25, 165. In practice, the masses and mixing angles for the neutralinos and charginos are best computed numerically. Note that the discussion above yields the tree-level masses. Loop corrections to these masses can be significant, and have been found systematically at one-loop order in ref. 182.

7.3 The gluino

The gluino is a color octet fermion, so it cannot mix with any other particle in the MSSM, even if $R$-parity is violated. In this regard, it is unique among all of the MSSM sparticles. In models with minimal supergravity or gauge-mediated boundary conditions, the gluino mass parameter $M_3$ is related to the bino and wino mass parameters $M_1$ and $M_2$ by eq. (5.49), so

$$M_3 = \frac{\alpha_s}{\alpha} \sin^2 \theta_W M_2 = \frac{3 \alpha_s}{5 \alpha} \cos^2 \theta_W M_1 \quad (7.49)$$

at any RG scale, up to small two-loop corrections. This implies a rough prediction

$$M_3 : M_2 : M_1 \approx 6 : 2 : 1 \quad (7.50)$$

near the TeV scale. It is therefore reasonable to suspect that the gluino is considerably heavier than the lighter neutralinos and charginos (even in many models where the gaugino mass unification condition is not imposed).

For more precise estimates, one must take into account the fact that $M_3$ is really a running mass parameter with an implicit dependence on the RG scale $Q$. Because the gluino is a strongly interacting
particle, $M_3$ runs rather quickly with $Q$ [see eq. (7.48)]. A more useful quantity physically is the RG scale-independent mass $m_\tilde{g}$ at which the renormalized gluino propagator has a pole. Including one-loop corrections to the gluino propagator due to gluon exchange and quark-squark loops, one finds that the pole mass is given in terms of the running mass in the DR scheme by [109]

$$m_\tilde{g} = M_3(Q) \left( 1 + \frac{\alpha_s}{4\pi} \left[ 15 + 6 \ln(Q/M_3) + \sum A_\tilde{q} \right] \right)$$  \hspace{1cm} (7.51)

where

$$A_\tilde{q} = \int_0^1 dx x \ln[xm_\tilde{g}^2/M_3^2 + (1-x)m_\tilde{q}^2/M_3^2 - x(1-x) - i\epsilon].$$  \hspace{1cm} (7.52)

The sum in eq. (7.51) is over all 12 squark-quark supermultiplets, and we have neglected small effects due to squark mixing. [As a check, requiring $m_\tilde{g}$ to be independent of $Q$ in eq. (7.51) reproduces the one-loop RG equation for $M_3(Q)$ in eq. (5.48).] The correction terms proportional to $\alpha_s$ in eq. (7.51) can be quite significant, because the gluino is strongly interacting, with a large group theory factor [the 15 in eq. (7.51)] due to its color octet nature, and because it couples to all of the squark-quark pairs. The leading two-loop corrections to the gluino pole mass have also been found [183], and typically increase the prediction by another 1 or 2%.

### 7.4 The squarks and sleptons

In principle, any scalars with the same electric charge, $R$-parity, and color quantum numbers can mix with each other. This means that with completely arbitrary soft terms, the mass eigenstates of the squarks and sleptons of the MSSM should be obtained by diagonalizing three $6 \times 6$ squared-mass matrices for up-type squarks ($\tilde{u}_L, \tilde{c}_L, \tilde{t}_L, \tilde{u}_R, \tilde{c}_R, \tilde{t}_R$), down-type squarks ($\tilde{d}_L, \tilde{s}_L, \tilde{b}_L, \tilde{d}_R, \tilde{s}_R, \tilde{b}_R$), and charged sleptons ($\tilde{e}_L, \tilde{\mu}_L, \tilde{\tau}_L, \tilde{e}_R, \tilde{\mu}_R, \tilde{\tau}_R$), and one $3 \times 3$ matrix for sneutrinos ($\tilde{\nu}_e, \tilde{\nu}_\mu, \tilde{\nu}_\tau$). Fortunately, the general hypothesis of flavor-blind soft parameters eqs. (5.18) and (5.19) predicts that most of these mixing angles are very small. The third-family squarks and sleptons can have very different masses compared to their first- and second-family counterparts, because of the effects of large Yukawa ($y_t, y_b, y_\tau$) and soft ($a_t, a_b, a_\tau$) couplings in the RG equations (5.63)-(5.67). Furthermore, they can have substantial mixing in pairs $(\tilde{t}_L, \tilde{t}_R), (\tilde{b}_L, \tilde{b}_R)$ and $(\tilde{\tau}_L, \tilde{\tau}_R)$. In contrast, the first- and second-family squarks and sleptons have negligible Yukawa couplings, so they end up in 7 very nearly degenerate, unmixed pairs ($\tilde{e}_R, \tilde{\mu}_R, (\tilde{\nu}_e, \tilde{\nu}_\mu), (\tilde{e}_L, \tilde{\nu}_\mu), (\tilde{\nu}_e, \tilde{\nu}_\mu), (\tilde{d}_R, \tilde{s}_R), (\tilde{u}_L, \tilde{c}_L), (\tilde{d}_L, \tilde{s}_L)$). As we have already discussed in section 7.4, this avoids the problem of disastrously large virtual sparticle contributions to flavor-changing processes.

Let us first consider the spectrum of first- and second-family squarks and sleptons. In many models, including both minimal supergravity [eq. (6.39)] and gauge-mediated [eq. (6.55)] boundary conditions, their running squared masses can be conveniently parameterized, to a good approximation, as:

$$m_{Q_1}^2 = m_{Q_2}^2 = m_0^2 + K_3 + K_2 + \frac{1}{36}K_1,$$  \hspace{1cm} (7.53)

$$m_{\tilde{u}_1}^2 = m_{\tilde{u}_2}^2 = m_0^2 + K_3 + \frac{4}{9}K_1,$$  \hspace{1cm} (7.54)

$$m_{\tilde{d}_1}^2 = m_{\tilde{d}_2}^2 = m_0^2 + K_3 + \frac{1}{9}K_1,$$  \hspace{1cm} (7.55)

$$m_{L_1}^2 = m_{L_2}^2 = m_0^2 + K_2 + \frac{1}{4}K_1,$$  \hspace{1cm} (7.56)

$$m_{\tilde{\nu}_1}^2 = m_{\tilde{\nu}_2}^2 = m_0^2 + K_1.$$  \hspace{1cm} (7.57)

A key point is that the same $K_3, K_2$ and $K_1$ appear everywhere in eqs. (7.53)-(7.57), since all of the chiral supermultiplets couple to the same gauginos with the same gauge couplings. The different
coefficients in front of $K_1$ just correspond to the various values of weak hypercharge squared for each scalar.

In minimal supergravity models, $m_0^2$ is the same common scalar squared mass appearing in eq. (6.39). It can be very small, as in the “no-scale” limit, but it could also be the dominant source of the scalar masses. The contributions $K_3$, $K_2$ and $K_1$ are due to the RG running\footnote{The quantity $S$ defined in eq. (5.51) vanishes for both minimal supergravity and gauge-mediated boundary conditions, and remains small under RG evolution.} proportional to the gaugino masses. Explicitly, they are found at one loop order by solving eq. (5.56):

$$K_a(Q) = \left\{ \begin{array}{l} 3/5 \\ 3/4 \\ 4/3 \\ \end{array} \right\} \times \frac{1}{2\pi^2} \int_{\ln Q_0}^{\ln Q_a} dt \, g_a^2(t) |M_a(t)|^2 \quad (a = 1, 2, 3).$$

(7.58)

Here $Q_0$ is the input RG scale at which the minimal supergravity boundary condition eq. (6.39) is applied, and $Q$ should be taken to be evaluated near the squark and slepton mass under consideration, presumably less than about 1 TeV. The running parameters $g_a(Q)$ and $M_a(Q)$ obey eqs. (5.21) and (5.24). If the input scale is approximated by the apparent scale of gauge coupling unification $Q_0 = M_U \approx 2 \times 10^{16}$ GeV, one finds that numerically

$$K_1 \approx 0.15m_{1/2}^2, \quad K_2 \approx 0.5m_{1/2}^2, \quad K_3 \approx (4.5 \to 6.5)m_{1/2}^2.$$ 

(7.59)

for $Q$ near the electroweak scale. Here $m_{1/2}$ is the common gaugino mass parameter at the unification scale. Note that $K_3 \gg K_2 \gg K_1$; this is a direct consequence of the relative sizes of the gauge couplings $g_3, g_2,$ and $g_1$. The large uncertainty in $K_3$ is due in part to the experimental uncertainty in the QCD coupling constant, and in part to the uncertainty in where to choose $Q$, since $K_3$ runs rather quickly below 1 TeV. If the gauge couplings and gaugino masses are unified between $M_U$ and $M_P$, as would occur in a GUT model, then the effect of RG running for $M_U < Q < M_P$ can be absorbed into a redefinition of $m_0^2$. Otherwise, it adds a further uncertainty roughly proportional to $\ln(M_P/M_U)$, compared to the larger contributions in eq. (7.58), which go roughly like $\ln(M_U/1 \text{ TeV})$.

In gauge-mediated models, the same parameterization eqs. (6.53-6.57) holds, but $m_0^2$ is always 0. At the input scale $Q_0$, each MSSM scalar gets contributions to its squared mass that depend only on its gauge interactions, as in eq. (6.55). It is not hard to see that in general these contribute in exactly the same pattern as $K_1$, $K_2$, and $K_3$ in eq. (6.53-6.57). The subsequent evolution of the scalar squared masses down to the electroweak scale again just yields more contributions to the $K_1$, $K_2$, and $K_3$ parameters. It is somewhat more difficult to give meaningful numerical estimates for these parameters in gauge-mediated models than in the minimal supergravity models without knowing the messenger mass scale(s) and the multiplicities of the messenger fields. However, in the gauge-mediated case one quite generally expects that the numerical values of the ratios $K_3/K_2$, $K_3/K_1$ and $K_2/K_1$ should be even larger than in eq. (7.59). There are two reasons for this. First, the running squark squared masses start off larger than slepton squared masses already at the input scale in gauge-mediated models, rather than having a common value $m_0^2$. Furthermore, in the gauge-mediated case, the input scale $Q_0$ is typically much lower than $M_P$ or $M_U$, so that the RG evolution gives relatively more weight to RG scales closer to the electroweak scale, where the hierarchies $g_3 > g_2 > g_1$ and $M_3 > M_2 > M_1$ are already in effect.

In general, one therefore expects that the squarks should be considerably heavier than the sleptons, with the effect being more pronounced in gauge-mediated supersymmetry breaking models than in minimal supergravity models. For any specific choice of model, this effect can be easily quantified with a numerical RG computation. The hierarchy $m_{\text{squark}} > m_{\text{slepton}}$ tends to hold even in models that do not fit neatly into any of the categories outlined in section 6 because the RG contributions to squark masses from the gluino are always present and usually quite large, since QCD has a larger gauge coupling than the electroweak interactions.
Regardless of the type of model, there is also a “hyperfine” splitting in the squark and slepton mass spectrum produced by electroweak symmetry breaking. Each squark and slepton \( \phi \) will get a contribution \( \Delta_{\phi} \) to its squared mass, coming from the \( SU(2)_L \) and \( U(1)_Y \) D-term quartic interactions [see the last term in eq. (7.73)] of the form \((\text{squark})^2(\text{Higgs})^2 \) and \((\text{slepton})^2(\text{Higgs})^2 \), when the neutral Higgs scalars \( H_u^0 \) and \( H_d^0 \) get VEVs. They are model-independent for a given value of \( \tan \beta \):

\[
\Delta_{\phi} = (T_{3\phi} g^2 - Y_{\phi} g^2)(v_u^2 - v_d^2) = (T_{3\phi} - Q_{\phi} \sin^2 \theta_W) \cos(2\beta) m_Z^2,
\]

where \( T_{3\phi}, Y_{\phi}, \) and \( Q_{\phi} \) are the third component of weak isospin, the weak hypercharge, and the electric charge of the left-handed chiral supermultiplet to which \( \phi \) belongs. For example, \( \Delta_{\tilde{d}_L} = (\frac{1}{2} - \frac{2}{3} \sin^2 \theta_W) \cos(2\beta) m_Z^2 \) and \( \Delta_{\tilde{u}_L} = (-\frac{1}{2} + \frac{2}{3} \sin^2 \theta_W) \cos(2\beta) m_Z^2 \) and \( \Delta_{\tilde{d}_R} = (\frac{2}{3} \sin^2 \theta_W) \cos(2\beta) m_Z^2 \). These D-term contributions are typically smaller than the \( m_0^2 \) and \( K_1, K_2, K_3 \) contributions, but should not be neglected. They split apart the components of the \( SU(2)_L \)-doublet sleptons and squarks. Including them, the first-family squark and slepton masses are now given by:

\[
m_{\tilde{d}_L}^2 = m_0^2 + K_3 + K_2 + \frac{1}{36} K_1 + \Delta_{\tilde{d}_L},
\]

\[
m_{\tilde{u}_L}^2 = m_0^2 + K_3 + K_2 + \frac{1}{36} K_1 + \Delta_{\tilde{u}_L},
\]

\[
m_{\tilde{d}_R}^2 = m_0^2 + K_3 + \frac{4}{9} K_1 + \Delta_{\tilde{d}_R},
\]

\[
m_{\tilde{u}_R}^2 = m_0^2 + K_3 + \frac{1}{9} K_1 + \Delta_{\tilde{u}_R},
\]

\[
m_{\tilde{e}_L}^2 = m_0^2 + K_2 + \frac{1}{4} K_1 + \Delta_{\tilde{e}_L},
\]

\[
m_{\tilde{e}_R}^2 = m_0^2 + K_2 + \frac{1}{4} K_1 + \Delta_{\tilde{e}_R},
\]

with identical formulas for the second-family squarks and sleptons. The mass splittings for the left-handed squarks and sleptons are governed by model-independent sum rules

\[
m_{\tilde{e}_L}^2 - m_{\tilde{e}_R}^2 = m_{\tilde{d}_L}^2 - m_{\tilde{u}_L}^2 = g^2 (v_u^2 - v_d^2)/2 = -\cos(2\beta) m_W^2.
\]

In the allowed range \( \tan \beta > 1 \), it follows that \( m_{\tilde{d}_L} > m_{\tilde{u}_L} \) and \( m_{\tilde{d}_R} > m_{\tilde{u}_L} \), with the magnitude of the splittings constrained by electroweak symmetry breaking.

Let us next consider the masses of the top squarks, for which there are several non-negligible contributions. First, there are squared-mass terms for \( \tilde{t}_L \tilde{t}_L \) and \( \tilde{t}_R \tilde{t}_R \) that are just equal to \( m_{Q_3}^2 + \Delta_{\tilde{u}_L} \) and \( m_{D_3}^2 + \Delta_{\tilde{d}_R} \), respectively, just as for the first- and second-family squarks. Second, there are contributions equal to \( m_t^2 \) for each of \( \tilde{t}_L \tilde{t}_L \) and \( \tilde{t}_R \tilde{t}_R \). These come from F-terms in the scalar potential of the form \( y_t^2 H_u^{0*} H_u^0 \tilde{t}_L \tilde{t}_L \) and \( y_t^2 H_d^{0*} H_d^0 \tilde{t}_R \tilde{t}_R \) (see Figures 5.2b and 5.2c), with the Higgs fields replaced by their VEVs. (Of course, similar contributions are present for all of the squarks and sleptons, but they are too small to worry about except in the case of the top squarks.) Third, there are contributions to the scalar potential from F-terms of the form \( -\mu_t^2 v_t \tilde{t}_L^* \tilde{t}_L + c.c. \); see eqs. (5.10) and Figure 5.4a. These become \( -\mu_t^2 v_t \cos \beta \tilde{t}_R^* \tilde{t}_L + c.c. \) when \( H_d^0 \) is replaced by its VEV. Finally, there are contributions to the scalar potential from the soft (scalar) \( \beta \) couplings \( a_t^0 \tilde{Q}_3 H_u^0 + c.c. \) [see the first term of the second line of eq. (5.12), and eq. (5.50)], which become \( a_t^0 v_\beta \sin \beta \tilde{t}_L \tilde{t}_R + c.c. \) when \( H_u^0 \) is replaced by its VEV. Putting these all together, we have a squared-mass matrix for the top squarks, which in the gauge-eigenstate basis \( (\tilde{t}_L, \tilde{t}_R) \) is given by

\[
\mathcal{L} \text{ stop masses} = - (\tilde{t}_L \tilde{t}_R) \left( \begin{array}{c} m_t^2 \\ \frac{\tilde{t}_L}{\tilde{t}_R} \end{array} \right)
\]
where

\[
m_t^2 = \begin{pmatrix}
m_{Q_1}^2 + m_t^2 + \Delta \bar{\alpha}_L & v(a_t^* \sin \beta - \mu y_t \cos \beta) \\
v(a_t \sin \beta - \mu^* y_t \cos \beta) & m_{d_3}^2 + m_t^2 + \Delta \bar{\alpha}_R
\end{pmatrix}.
\]  

(7.70)

This hermitian matrix can be diagonalized by a unitary matrix to give mass eigenstates:

\[
\begin{pmatrix}
\tilde{t}_1 \\
\tilde{t}_2
\end{pmatrix} = \begin{pmatrix}
c_t & -s_t \\
s_t & c_t
\end{pmatrix} \begin{pmatrix}
\tilde{t}_L \\
\tilde{t}_R
\end{pmatrix}.
\]  

(7.71)

Here \(m_{\tilde{t}_1}^2 < m_{\tilde{t}_2}^2\) are the eigenvalues of eq. (7.70), and \(|c_t|^2 + |s_t|^2 = 1\). If the off-diagonal elements of eq. (7.70) are real, then \(c_t\) and \(s_t\) are the cosine and sine of a stop mixing angle \(\theta_t\), which can be chosen in the range \(0 \leq \theta_t < \pi\). Because of the large RG effects proportional to \(X_t\) in eq. (5.63) and eq. (5.64), at the electroweak scale one finds that \(m_{\tilde{t}_1}^2 < m_{\tilde{t}_3}^2\), and both of these quantities are usually significantly smaller than the squark squared masses for the first two families. The diagonal terms \(m_t^2\) in eq. (7.70) tend to mitigate this effect somewhat, but the off-diagonal entries will typically induce a significant mixing, which always reduces the lighter top-squark squared-mass eigenvalue. Therefore, models often predict that \(\tilde{t}_1\) is the lightest squark of all, and that it is predominantly \(\tilde{t}_L\).

A very similar analysis can be performed for the bottom squarks and charged tau sleptons, which in their respective gauge-eigenstate bases \((\bar{b}_L, \bar{b}_R)\) and \((\bar{\tau}_L, \bar{\tau}_R)\) have squared-mass matrices:

\[
m_b^2 = \begin{pmatrix}
m_{Q_3}^2 + \Delta d_L & v(a_b^* \cos \beta - \mu y_b \sin \beta) \\
v(a_b \cos \beta - \mu^* y_b \sin \beta) & m_{d_3}^2 + \Delta \bar{\alpha}_R
\end{pmatrix},
\]  

(7.72)

\[
m_\tau^2 = \begin{pmatrix}
m_{L_3}^2 + \Delta \bar{\alpha}_L & v(a_\tau^* \cos \beta - \mu y_\tau \sin \beta) \\
v(a_\tau \cos \beta - \mu^* y_\tau \sin \beta) & m_{d_3}^2 + \Delta \bar{\alpha}_R
\end{pmatrix}.
\]  

(7.73)

These can be diagonalized to give mass eigenstates \(\tilde{b}_1, \tilde{b}_2\) and \(\tilde{\tau}_1, \tilde{\tau}_2\) in exact analogy with eq. (7.71).

The magnitude and importance of mixing in the sbottom and stau sectors depends on how big \(\tan \beta\) is. If \(\tan \beta\) is not too large (in practice, this usually means less than about 10 or so, depending on the situation under study), the sbottoms and staus do not get a very large effect from the mixing terms and the RG effects due to \(X_b\) and \(X_\tau\), because \(y_b, y_\tau \ll y_t\) from eq. (5.63). In that case the mass eigenstates are very nearly the same as the gauge eigenstates \(\bar{b}_L, \bar{b}_R, \bar{\tau}_L, \bar{\tau}_R\). The latter three, and \(\bar{\nu}_\tau\), will be nearly degenerate with their first- and second-family counterparts with the same \(SU(3)_C \times SU(2)_L \times U(1)_Y\) quantum numbers. However, even in the case of small \(\tan \beta\), \(\bar{b}_L\) will feel the effects of the large top Yukawa coupling because it is part of the doublet containing \(\tilde{t}_L\). In particular, from eq. (5.63) we see that \(X_t\) acts to decrease \(m_{Q_3}^2\) as it is RG-evolved down from the input scale to the electroweak scale. Therefore the mass of \(\bar{b}_L\) can be significantly less than the masses of \(\bar{d}_L, \bar{s}_L\).

For larger values of \(\tan \beta\), the mixing in eqs. (7.72) and (7.73) can be quite significant, because \(y_b, y_\tau\) and \(a_b, a_\tau\) are non-negligible. Just as in the case of the top squarks, the lighter sbottom and stau mass eigenstates (denoted \(\tilde{b}_1\) and \(\tilde{\tau}_1\)) can be significantly lighter than their first- and second-family counterparts. Furthermore, \(\bar{\nu}_\tau\) can be significantly lighter than the nearly degenerate \(\bar{\nu}_t, \bar{\nu}_\mu\).

The requirement that the third-family squarks and sleptons should all have positive squared masses implies limits on the magnitudes of \(a_t^* \sin \beta - \mu y_t \cos \beta\) and \(a_b^* \cos \beta - \mu y_b \sin \beta\), and on \(a_\tau^* \cos \beta - \mu y_\tau \sin \beta\). If they are too large, then the smaller eigenvalue of eq. (7.70), (7.72) or (7.73) will be driven negative, implying that a squark or charged slepton gets a VEV, breaking \(SU(3)_C\) or electromagnetism. Since this is clearly unacceptable, one can put bounds on the (scalar)\(^3\) couplings, or equivalently on the parameter \(A_0\) in minimal supergravity models. Even if all of the squared-mass eigenvalues are positive, the presence of large (scalar)\(^3\) couplings can yield global minima of the scalar potential, with non-zero squark and/or charged slepton VEVs, which are disconnected from the vacuum that conserves \(SU(3)_C\).
and electromagnetism [184]. However, it is not always immediately clear whether the mere existence of such disconnected global minima should really disqualify a set of model parameters, because the tunneling rate from our “good” vacuum to the “bad” vacua can easily be longer than the age of the universe [185].

### 7.5 Summary: the MSSM sparticle spectrum

In the MSSM there are 32 distinct masses corresponding to undiscovered particles, not including the gravitino. In this section we have explained how the masses and mixing angles for these particles can be computed, given an underlying model for the soft terms at some input scale. Assuming only that the mixing of first- and second-family squarks and sleptons is negligible, the mass eigenstates of the MSSM are listed in Table 7.1. A complete set of Feynman rules for the interactions of these particles with each other and with the Standard Model quarks, leptons, and gauge bosons can be found in refs. [25, 165]. Specific models for the soft terms typically predict the masses and the mixing angles angles for the MSSM in terms of far fewer parameters. For example, in the minimal supergravity models, the only parameters not already measured by experiment are $m_0^2$, $m_{1/2}$, $A_0$, $\mu$, and $b$. In gauge-mediated supersymmetry breaking models, the free parameters include at least the scale $\Lambda$, the typical messenger mass scale $M_{\text{mess}}$, the integer number $N_5$ of copies of the minimal messengers, the goldstino decay constant $\langle F \rangle$, and the Higgs mass parameters $\mu$ and $b$. After RG evolving the soft terms down to the electroweak scale, one can demand that the scalar potential gives correct electroweak symmetry breaking. This allows us to trade $|\mu|$ and $b$ (or $B_0$) for one parameter $\tan \beta$, as in eqs. (7.9)-(7.8). So, to a reasonable approximation, the entire mass spectrum in minimal supergravity models is determined by only five unknown parameters: $m_0^2$, $m_{1/2}$, $A_0$, $\tan \beta$, and Arg($\mu$), while in the simplest gauge-mediated supersymmetry breaking models one can pick parameters $\Lambda$, $M_{\text{mess}}$, $N_5$, $\langle F \rangle$, $\tan \beta$, and Arg($\mu$). Both frameworks are highly predictive. Of course, it is easy to imagine that the essential physics of supersymmetry breaking is not captured by either of these two scenarios in their minimal forms. For example, the anomaly mediated contributions could play a role, perhaps in concert with the gauge-mediation or Planck-scale mediation mechanisms.

Table 7.1: The undiscovered particles in the Minimal Supersymmetric Standard Model (with sfermion mixing for the first two families assumed to be negligible).
Figure 7.4: RG evolution of scalar and gaugino mass parameters in the MSSM with typical minimal supergravity-inspired boundary conditions imposed at $Q_0 = 2.5 \times 10^{16}$ GeV. The parameter $\mu^2 + m_{H_u}^2$ runs negative, provoking electroweak symmetry breaking.

Figure 7.4 shows the RG running of scalar and gaugino masses in a typical model based on the minimal supergravity boundary conditions imposed at $Q_0 = 2.5 \times 10^{16}$ GeV. [The parameter values used for this illustration were $m_0 = 80$ GeV, $m_{1/2} = 250$ GeV, $A_0 = -500$ GeV, $\tan \beta = 10$, and sign($\mu$) = +.] The running gaugino masses are solid lines labeled by $M_1$, $M_2$, and $M_3$. The dot-dashed lines labeled $H_u$ and $H_d$ are the running values of the quantities $(\mu^2 + m_{H_u}^2)^{1/2}$ and $(\mu^2 + m_{H_d}^2)^{1/2}$, which appear in the Higgs potential. The other lines are the running squark and slepton masses, with dashed lines for the square roots of the third family parameters $m_{d_3}^2$, $m_{Q_3}^2$, $m_{\tilde{b}_1}^2$, $m_{\tilde{e}_3}^2$, and $m_{\tilde{\tau}_3}^2$ (from top to bottom), and solid lines for the first and second family sfermions. Note that $\mu^2 + m_{H_u}^2$ runs negative because of the effects of the large top Yukawa coupling as discussed above, providing for electroweak symmetry breaking. At the electroweak scale, the values of the Lagrangian soft parameters can be used to extract the physical masses, cross-sections, and decay widths of the particles, and other observables such as dark matter abundances and rare process rates. There are a variety of publicly available programs that do these tasks, including radiative corrections; see for example [186]-[195],[177].

Figure 7.5 shows deliberately qualitative sketches of sample MSSM mass spectrum obtained from three different types of models assumptions. The first is the output from a minimal supergravity-inspired model with relatively low $m_0^2$ compared to $m_{1/2}^2$ (in fact the same model parameters as used for fig. 7.4). This model features a near-decoupling limit for the Higgs sector, and a bino-like $\tilde{\chi}_1^0$, nearly degenerate wino-like $\tilde{\chi}_2^\pm, \tilde{\chi}_1^\pm$, and higgsino-like $\tilde{\chi}_3^0, \tilde{\chi}_4^0, \tilde{\chi}_2^0$. The gluino is the heaviest superpartner. The squarks are all much heavier than the sleptons, and the lightest sfermion is a stau. Variations in the model parameters have important and predictable effects. For example, taking larger $m_0^2$ in minimal supergravity models will tend to squeeze together the spectrum of squarks and sleptons and move them all higher compared to the neutralinos, charginos and gluino. Taking larger values of $\tan \beta$ with other model parameters held fixed will usually tend to lower $\tilde{b}_1$ and $\tilde{\tau}_1$ masses compared to those of the other sparticles.

The second sample sketch in fig. 7.5 is obtained from a typical minimal GMSB model, with boundary
Figure 7.5: Three sample schematic mass spectra for the undiscovered particles in the MSSM, for (a) minimal supergravity with $m_0^2 \ll m_{1/2}^2$, (b) minimal GMSB with $N_5 = 1$, and (c) AMSB with an extra $m_0^2$ for scalars. These spectra are presented for entertainment purposes only! No warranty, expressed or implied, guarantees that they look anything like the real world.
conditions as in eq. \[ (6.62) \] [with \( N_5 = 1, \Lambda = 150 \text{ TeV}, \tan \beta = 15, \text{ and } \text{sign}(\mu) = + \) at a scale \( Q_0 = M_{\text{mess}} = 300 \text{ TeV} \) for the illustration]. Here we see that the hierarchy between strongly interacting sparticles and weakly interacting ones is quite large. Changing the messenger scale or \( \Lambda \) does not reduce the relative splitting between squark and slepton masses, because there is no analog of the universal \( m_0^2 \) contribution here. Increasing the number of messenger fields tends to decrease the squark and slepton masses relative to the gaugino masses, but still keeps the hierarchy between squark and slepton masses intact. In the model shown, the NLSP is a bino-like neutralino, but for larger number of messenger fields it could be either a stau, or else co-NLSPs \( \tilde{\tau}, \tilde{e}_L, \tilde{\mu}_L \), depending on the choice of \( \tan \beta \).

The third sample sketch in fig. \[ 7.6 \] is obtained from an AMSB model with an additional universal scalar mass \( m_0 = 450 \text{ TeV} \) added at \( Q_0 = 2 \times 10^{16} \text{ GeV} \) to rescue the sleptons, and with \( m_{3/2} = 60 \text{ TeV}, \tan \beta = 10, \) and \( \text{sign}(\mu) = + \) for the illustration. Here the most striking feature is that the LSP is a wino-like neutralino, with \( m_{\tilde{C}_1} - m_{\tilde{N}_1} \) only about 160 MeV.

It would be a mistake to rely too heavily on specific scenarios for the MSSM mass and mixing spectrum, and the above illustrations are only a tiny fraction of the available possibilities. However, it is also useful to keep in mind some general lessons that often recur in various different models. Indeed, there has emerged a sort of folklore concerning likely features of the MSSM spectrum, partly based on theoretical bias and partly on the constraints inherent in most known viable softly-broken supersymmetric theories. We remark on these features mainly because they represent the prevailing prejudices among supersymmetry theorists, which is certainly a useful thing to know even if one wisely decides to remain skeptical. For example, it is perhaps not unlikely that:

- The LSP is the lightest neutralino \( \tilde{N}_1 \), unless the gravitino is lighter or \( R \)-parity is not conserved. If \( M_1 < M_2, |\mu|, \) then \( \tilde{N}_1 \) is likely to be bino-like, with a mass roughly 0.5 times the masses of \( \tilde{N}_2 \) and \( \tilde{C}_1 \) in many well-motivated models. If, instead, \( |\mu| < M_1, M_2, \) then the LSP \( \tilde{N}_1 \) has a large higgsino content and \( \tilde{N}_2 \) and \( \tilde{C}_1 \) are not much heavier. And, if \( M_2 \ll M_1, |\mu|, \) then the LSP will be a wino-like neutralino, with a chargino only very slightly heavier.

- The gluino will be much heavier than the lighter neutralinos and charginos. This is certainly true in the case of the “standard” gaugino mass relation eq. \[ (5.49) \]; more generally, the running gluino mass parameter grows relatively quickly as it is RG-evolved into the infrared because the QCD coupling is larger than the electroweak gauge couplings. So even if there are big corrections to the gaugino mass boundary conditions eqs. \[ (6.68) \] or \[ (6.63) \], the gluino mass parameter \( M_3 \) is likely to come out larger than \( M_1 \) and \( M_2 \).

- The squarks of the first and second families are nearly degenerate and much heavier than the sleptons. This is because each squark mass gets the same large positive-definite radiative corrections from loops involving the gluino. The left-handed squarks \( \tilde{u}_L, \tilde{d}_L, \tilde{s}_L \) and \( \tilde{c}_L \) are likely to be heavier than their right-handed counterparts \( \tilde{u}_R, \tilde{d}_R, \tilde{s}_R \) and \( \tilde{c}_R \), because of the effect parameterized by \( K_2 \) in eqs. \[ (7.61)-(7.67) \].

- The squarks of the first two families cannot be lighter than about 0.8 times the mass of the gluino in minimal supergravity models, and about 0.6 times the mass of the gluino in the simplest gauge-mediated models as discussed in section \[ 6.7 \] if the number of messenger squark pairs is \( N_5 \leq 4 \). In the minimal supergravity case this is because the gluino mass feeds into the squark masses through RG evolution; in the gauge-mediated case it is because the gluino and squark masses are tied together by eqs. \[ (6.58) \] and \[ (6.59) \].

- The lighter stop \( \tilde{t}_1 \) and the lighter sbottom \( \tilde{b}_1 \) are probably the lightest squarks. This is because stop and sbottom mixing effects and the effects of \( X_t \) and \( X_b \) in eqs. \[ (5.63)-(5.65) \] both tend to decrease the lighter stop and sbottom masses.

81
• The lightest charged slepton is probably a stau $\tilde{\tau}_1$. The mass difference $m_{\tilde{e}_R} - m_{\tilde{e}_L}$ is likely to be significant if $\tan \beta$ is large, because of the effects of a large tau Yukawa coupling. For smaller $\tan \beta$, $\tilde{\tau}_1$ is predominantly $\tilde{\tau}_R$ and it is not so much lighter than $\tilde{e}_R$, $\tilde{\mu}_R$.

• The left-handed charged sleptons $\tilde{e}_L$ and $\tilde{\mu}_L$ are likely to be heavier than their right-handed counterparts $\tilde{e}_R$ and $\tilde{\mu}_R$. This is because of the effect of $K_2$ in eq. (7.65). (Note also that $\Delta \tilde{e}_L - \Delta \tilde{e}_R$ is positive but very small because of the numerical accident $\sin^2 \theta_W \approx 1/4$.)

• The lightest neutral Higgs boson $h^0$ should be lighter than about 150 GeV, and may be much lighter than the other Higgs scalar mass eigenstates $A^0$, $H^\pm$, $H^0$.

The most important point is that by measuring the masses and mixing angles of the MSSM particles we will be able to gain a great deal of information that can rule out or bolster evidence for competing proposals for the origin and mediation of supersymmetry breaking.

8 Sparticle decays

This section contains a brief qualitative overview of the decay patterns of sparticles in the MSSM, assuming that $R$-parity is conserved. We will consider in turn the possible decays of neutralinos, charginos, sleptons, squarks, and the gluino. If, as is most often assumed, the lightest neutralino $\tilde{N}_1$ is the LSP, then all decay chains will end up with it in the final state. Section 8.5 discusses the alternative possibility that the gravitino/goldstino $\tilde{G}$ is the LSP. For the sake of simplicity of notation, we will often not distinguish between particle and antiparticle names and labels in this section, with context and consistency (dictated by charge and color conservation) resolving any ambiguities.

8.1 Decays of neutralinos and charginos

Let us first consider the possible two-body decays. Each neutralino and chargino contains at least a small admixture of the electroweak gauginos $B$, $W^0$ or $W^\pm$, as we saw in section 7.3. So $\tilde{N}_1$ and $\tilde{C}_1$ inherit couplings of weak interaction strength to (scalar, fermion) pairs, as shown in Figure 5.3b,c. If sleptons or squarks are sufficiently light, a neutralino or chargino can therefore decay into lepton+slepton or quark+squark. To the extent that sleptons are probably lighter than squarks, the lepton+slepton final states are favored. A neutralino or chargino may also decay into any lighter neutralino or chargino plus a Higgs scalar or an electroweak gauge boson, because they inherit the gaugino-higgsino-Higgs (see Figure 5.3b,c) and $SU(2)_L$ gaugino-gaugino-vector boson (see Figure 5.3b) couplings of their components. So, the possible two-body decay modes for neutralinos and charginos in the MSSM are:

$$\tilde{N}_i \rightarrow Z \tilde{N}_j, \quad W \tilde{C}_j, \quad h^0 \tilde{N}_j, \quad \ell \tilde{\nu}, \quad \nu \tilde{\nu}, \quad [A^0 \tilde{N}_j, \quad H^0 \tilde{N}_j, \quad H^\pm \tilde{C}_j, \quad q \bar{q}], \quad (8.1)$$

$$\tilde{C}_i \rightarrow W \tilde{N}_j, \quad Z \tilde{C}_1, \quad h^0 \tilde{C}_1, \quad \ell \tilde{\nu}, \quad \nu \tilde{\nu}, \quad [A^0 \tilde{C}_1, \quad H^0 \tilde{C}_1, \quad H^\pm \tilde{N}_j, \quad q \bar{q}], \quad (8.2)$$

using a generic notation $\nu$, $\ell$, $q$ for neutrinos, charged leptons, and quarks. The final states in brackets are the more kinematically implausible ones. (Since $h^0$ is required to be light, it is the most likely of the Higgs scalars to appear in these decays. This could even be the best way to discover the Higgs.) For the heavier neutralinos and chargino ($\tilde{N}_3$, $\tilde{N}_4$ and $\tilde{C}_2$), one or more of the two-body decays in eqs. (8.1) and (8.2) is likely to be kinematically allowed. Also, if the decays of neutralinos and charginos with a significant higgsino content into third-family quark-squark pairs are open, they can be greatly enhanced by the top-quark Yukawa coupling, following from the interactions shown in fig. 5.1b,c.

It may be that all of these two-body modes are kinematically forbidden for a given chargino or neutralino, especially for $\tilde{C}_1$ and $\tilde{N}_2$ decays. In that case, they have three-body decays

$$\tilde{N}_i \rightarrow f f \tilde{N}_j, \quad \tilde{N}_i \rightarrow f f' \tilde{C}_j, \quad \tilde{C}_i \rightarrow f f' \tilde{N}_j, \quad \text{and} \quad \tilde{C}_2 \rightarrow f f \tilde{C}_1, \quad (8.3)$$
through the same (but now off-shell) gauge bosons, Higgs scalars, sleptons, and squarks that appeared in the two-body decays eqs. (8.1) and (8.2). Here \( f \) is generic notation for a lepton or quark, with \( f \) and \( f' \) distinct members of the same \( SU(2)_L \) multiplet (and of course one of the \( f \) or \( f' \) in each of these decays must actually be an antifermion). The chargino and neutralino decay widths into the various final states can be found in refs. [196]-[198].

The Feynman diagrams for the neutralino and chargino decays with \( \tilde{N}_1 \) in the final state that seem most likely to be important are shown in figure 8.1. In many situations, the decays

\[
\tilde{C}_1^\pm \rightarrow \ell^\pm \nu \tilde{N}_1, \quad \tilde{N}_2 \rightarrow \ell^+ \ell^- \tilde{N}_1
\]

(8.4)

can be particularly important for phenomenology, because the leptons in the final state often will result in clean signals. These decays are more likely if the intermediate sleptons are relatively light, even if they cannot be on-shell. Unfortunately, the enhanced mixing of staus, common in models, can often result in larger branching fractions for both \( \tilde{N}_2 \) and \( \tilde{C}_1 \) into final states with taus, rather than electrons or muons. This is one reason why tau identification may be a crucial limiting factor in attempts to discover and study supersymmetry.

In other situations, decays without isolated leptons in the final state are more useful, so that one will not need to contend with background events with missing energy coming from leptonic \( W \) boson decays in Standard Model processes. Then the decays of interest are the ones with quark partons in the final state, leading to

\[
\tilde{C}_1 \rightarrow jj \tilde{N}_1, \quad \tilde{N}_2 \rightarrow jj \tilde{N}_1,
\]

(8.5)

where \( j \) means a jet. If the second of these decays goes through an on-shell (or nearly so) \( h^0 \), then these will usually be \( b \)-jets.

8.2 Slepton decays

Sleptons can have two-body decays into a lepton and a chargino or neutralino, because of their gaugino admixture, as may be seen directly from the couplings in Figures 5.3b,c. Therefore, the two-body decays

\[
\ell \rightarrow \ell \tilde{N}_i, \quad \ell \rightarrow \nu \tilde{C}_i, \quad \nu \rightarrow \nu \tilde{N}_i, \quad \tilde{\nu} \rightarrow \ell \tilde{C}_i
\]

(8.6)

can be of weak interaction strength. In particular, the direct decays

\[
\ell \rightarrow \ell \tilde{N}_1 \quad \text{and} \quad \tilde{\nu} \rightarrow \nu \tilde{N}_1
\]

(8.7)

83
are (almost\(^1\)) always kinematically allowed if \(\tilde{N}_1\) is the LSP. However, if the sleptons are sufficiently heavy, then the two-body decays

\[
\tilde{\ell} \rightarrow \nu \tilde{C}_1, \quad \tilde{\ell} \rightarrow \ell \tilde{N}_2, \quad \tilde{\nu} \rightarrow \nu \tilde{N}_2, \quad \text{and} \quad \tilde{\nu} \rightarrow \ell \tilde{C}_1
\]

(8.8)
can be important. The right-handed sleptons do not have a coupling to the \(SU(2)_L\) gauginos, so they typically prefer the direct decay \(\tilde{\ell}_R \rightarrow \ell \tilde{N}_1\), if \(\tilde{N}_1\) is bino-like. In contrast, the left-handed sleptons may prefer to decay as in eq. 8.8, rather than the direct decays to the LSP as in eq. 8.7, if the former is kinematically open and if \(\tilde{C}_1\) and \(\tilde{N}_2\) are mostly wino. This is because the slepton-lepton-wino interactions in Figure 5.3 are proportional to the \(SU(2)_L\) gauge coupling \(g\), whereas the slepton-lepton-bino interactions in Figure 5.3 are proportional to the much smaller \(U(1)_Y\) coupling \(g'\). Formulas for these decay widths can be found in ref. 197.

### 8.3 Squark decays

If the decay \(\tilde{q} \rightarrow \tilde{g} \tilde{g}\) is kinematically allowed, it will always dominate, because the quark-squark-gluino vertex in Figure 5.3 has QCD strength. Otherwise, the squarks can decay into a quark plus neutralino or chargino: \(\tilde{q} \rightarrow q \tilde{N}_1\) or \(q' \tilde{C}_1\). The direct decay to the LSP \(\tilde{q} \rightarrow q \tilde{N}_1\) is always kinematically favored, and for right-handed squarks it can dominate because \(\tilde{N}_1\) is mostly bino. However, the left-handed squarks may strongly prefer to decay into heavier charinos or neutralinos instead, for example \(\tilde{q} \rightarrow q \tilde{N}_2\) or \(q' \tilde{C}_1\), because the relevant squark-quark-wino couplings are much bigger than the squark-quark-bino couplings. Squark decays to higgsino-like charinos and neutralinos are less important, except in the cases of stops and sbottoms, which have sizable Yukawa couplings. The gluino, chargino or neutralino resulting from the squark decay will in turn decay, and so on, until a final state containing \(\tilde{N}_1\) is reached. This results in numerous and complicated decay chain possibilities called cascade decays 199.

It is possible that the decays \(\tilde{t}_1 \rightarrow \tilde{t} \tilde{g}\) and \(\tilde{t}_1 \rightarrow t \tilde{N}_1\) are both kinematically forbidden. If so, then the lighter top squark may decay only into charinos, by \(\tilde{t}_1 \rightarrow b \tilde{C}_1\). If even this decay is kinematically closed, then it has only the flavor-suppressed decay to a charm quark, \(\tilde{t}_1 \rightarrow c \tilde{N}_1\), and the four-body decay \(\tilde{t}_1 \rightarrow b f f' \tilde{N}_1\). These decays can be very slow 200, so that the lightest stop can be quasi-stable on the time scale relevant for collider physics, and can hadronize into bound states.

### 8.4 Gluino decays

The decay of the gluino can only proceed through a squark, either on-shell or virtual. If two-body decays \(\tilde{g} \rightarrow \tilde{q} \tilde{q}\) are open, they will dominate, again because the relevant gluino-quark-squark coupling in Figure 5.3 has QCD strength. Since the top and bottom squarks can easily be much lighter than all of the other squarks, it is quite possible that \(\tilde{g} \rightarrow t \tilde{t}_1\) and/or \(\tilde{g} \rightarrow b \tilde{b}_1\) are the only available two-body decay mode(s) for the gluino, in which case they will dominate over all others. If instead all of the squarks are heavier than the gluino, the gluino will decay only through off-shell squarks, so \(\tilde{g} \rightarrow q q \tilde{N}_i\) and \(q q' \tilde{C}_i\). The squarks, neutralinos and charginos in these final states will then decay as discussed above, so there can be many competing gluino decay chains. Some of the possibilities are shown in fig. 8.2. The cascade decays can have final-state branching fractions that are individually small and quite sensitive to the model parameters.

The simplest gluino decays, including the ones shown in fig. 8.2 can have 0, 1, or 2 charged leptons (in addition to two or more hadronic jets) in the final state. An important feature is that when there is exactly one charged lepton, it can have either charge with exactly equal probability. This follows from the fact that the gluino is a Majorana fermion, and does not “know” about electric charge; for each diagram with a given lepton charge, there is always an equal one with every particle replaced by its antiparticle.

\(^1\)An exception occurs if the mass difference \(m_{\tilde{t}_1} - m_{\tilde{N}_1}\) is less than \(m_\tau\).
8.5 Decays to the gravitino/goldstino

Most phenomenological studies of supersymmetry assume explicitly or implicitly that the lightest neutralino is the LSP. This is typically the case in gravity-mediated models for the soft terms. However, in gauge-mediated models (and in “no-scale” models), the LSP is instead the gravitino. As we saw in section 6.5, a very light gravitino may be relevant for collider phenomenology, because it contains as its longitudinal component the goldstino, which has a non-gravitational coupling to all sparticle-particle pairs \((\tilde{X}, X)\). The decay rate found in eq. (6.32) for \(\tilde{X} \rightarrow X\tilde{G}\) is usually not fast enough to compete with the other decays of particles \(\tilde{X}\) as mentioned above, except in the case that \(\tilde{X}\) is the next-to-lightest supersymmetric particle (NLSP). Since the NLSP has no competing decays, it should always decay into its superpartner and the LSP gravitino.

In principle, any of the MSSM superpartners could be the NLSP in models with a light goldstino, but most models with gauge mediation of supersymmetry breaking have either a neutralino or a charged lepton playing this role. The argument for this can be seen immediately from eqs. (6.58) and (6.59), since \(\alpha_1 < \alpha_2, \alpha_3\), those superpartners with only \(U(1)_Y\) interactions will tend to get the smallest masses. The gauge-eigenstate sparticles with this property are the bino and the right-handed sleptons \(\tilde{e}_R, \tilde{\mu}_R, \tilde{\tau}_R\), so the appropriate corresponding mass eigenstates should be plausible candidates for the NLSP.

First suppose that \(\tilde{N}_1\) is the NLSP in light goldstino models. Since \(\tilde{N}_1\) contains an admixture of the photino (the linear combination of bino and neutral wino whose superpartner is the photon), from eq. (6.32) it decays into photon + goldstino/gravitino with a partial width

\[
\Gamma(\tilde{N}_1 \rightarrow \gamma \tilde{G}) = 2 \times 10^{-3} \kappa_{1\gamma} \left( \frac{m_{\tilde{N}_1}}{100 \text{ GeV}} \right)^5 \left( \frac{\sqrt{\langle F \rangle}}{100 \text{ TeV}} \right)^{-4} \text{eV.} \tag{8.9}
\]

Here \(\kappa_{1\gamma} \equiv |N_{11}\cos\theta_W + N_{12}\sin\theta_W|^2\) is the “photino content” of \(\tilde{N}_1\), in terms of the neutralino mixing matrix \(N_{ij}\) defined by eq. (7.33). We have normalized \(m_{\tilde{N}_1}\) and \(\sqrt{\langle F \rangle}\) to (very roughly) minimum expected values in gauge-mediated models. This width is much smaller than for a typical flavor-unsuppressed weak interaction decay, but it is still large enough to allow \(\tilde{N}_1\) to decay before it has left a collider detector, if \(\sqrt{\langle F \rangle}\) is less than a few thousand TeV in gauge-mediated models, or equivalently if \(m_{3/2}\) is less than a keV or so when eq. (6.31) holds. In fact, from eq. (8.9), the mean...
decay length of an $\tilde{N}_1$ with energy $E$ in the lab frame is

$$d = 9.9 \times 10^{-3} \frac{1}{\kappa_{1\gamma}} (E^2/m_{\tilde{N}_1}^2 - 1)^{1/2} \left( \frac{m_{\tilde{N}_1}}{100 \text{ GeV}} \right)^{-5} \left( \frac{\sqrt{(F)}}{100 \text{ TeV}} \right)^4 \text{ cm}, \quad (8.10)$$

which could be anything from sub-micron to multi-kilometer, depending on the scale of supersymmetry breaking $\sqrt{(F)}$. (In other models that have a gravitino LSP, including certain “no-scale” models, the same formulas apply with $(F) \to \sqrt{3} m_{3/2} M_P$.)

Of course, $\tilde{N}_1$ is not a pure photino, but contains also admixtures of the superpartner of the $Z$ boson and the neutral Higgs scalars. So, one can also have $\tilde{N}_1 \to Z \tilde{G}, h^0 \tilde{G}, A^0 \tilde{G}$, or $H^0 \tilde{G}$, with decay widths given in ref. [128]. Of these decays, the last two are unlikely to be kinematically allowed, and only the $\tilde{N}_1 \to \gamma \tilde{G}$ mode is guaranteed to be kinematically allowed for a gravitino LSP. Furthermore, even if they are open, the decays $\tilde{N}_1 \to Z \tilde{G}$ and $\tilde{N}_1 \to h^0 \tilde{G}$ are subject to strong kinematic suppressions proportional to $(1 - m_Z^2/m_{\tilde{N}_1}^2)^4$ and $(1 - m_{h^0}^2/m_{\tilde{N}_1}^2)^4$, respectively, in view of eq. (6.32). Still, these decays may play an important role in phenomenology if $(F)$ is not too large, $\tilde{N}_1$ has a sizable zino or higgsino content, and $m_{\tilde{N}_1}$ is significantly greater than $m_Z$ or $m_{h^0}$.

A charged slepton makes another likely candidate for the NLSP. Actually, more than one slepton can act effectively as the NLSP, even though one of them is slightly lighter, if they are sufficiently close in mass so that each has no kinematically allowed decays except to the goldstino. In GMSB models, the squared masses obtained by $\tilde{e}_R$, $\tilde{\mu}_R$ and $\tilde{\tau}_R$ are equal because of the flavor-blindness of the gauge couplings. However, this is not the whole story, because one must take into account mixing with $\tilde{e}_L$, $\tilde{\mu}_L$, and $\tilde{\tau}_L$ and renormalization group running. These effects are very small for $\tilde{e}_R$ and $\tilde{\mu}_R$ because of the tiny electron and muon Yukawa couplings, so we can quite generally treat them as degenerate, unmixed mass eigenstates. In contrast, $\tilde{\tau}_R$ usually has a quite significant mixing with $\tilde{\tau}_L$, proportional to the tau Yukawa coupling. This means that the lighter stau mass eigenstate $\tilde{\tau}_1$ is pushed lower in mass than $\tilde{e}_R$ or $\tilde{\mu}_R$, by an amount that depends most strongly on $\tan \beta$. If $\tan \beta$ is not too large then the stau mixing effect leaves the slepton mass eigenstates $\tilde{e}_R$, $\tilde{\mu}_R$, and $\tilde{\tau}_1$ degenerate to within less than $m_\tau \approx 1.8$ GeV, so they act effectively as co-NLSPs. In particular, this means that even though the stau is slightly lighter, the three-body slepton decays $\tilde{e}_R \to e \tau^\pm \tilde{\tau}_1^\mp$ and $\tilde{\mu}_R \to \mu \tau^\pm \tilde{\tau}_1^\mp$ are not kinematically allowed; the only allowed decays for the three lightest sleptons are $\tilde{e}_R \to e \tilde{G}$ and $\tilde{\mu}_R \to \mu \tilde{G}$ and $\tilde{\tau}_1 \to \tau \tilde{G}$. This situation is called the “slepton co-NLSP” scenario.

For larger values of $\tan \beta$, the lighter stau eigenstate $\tilde{\tau}_1$ is more than 1.8 GeV lighter than $\tilde{e}_R$ and $\tilde{\mu}_R$ and $\tilde{N}_1$. This means that the decays $\tilde{N}_1 \to \tau \tilde{\tau}_1$ and $\tilde{e}_R \to e \tilde{\tau}_1$ and $\tilde{\mu}_R \to \mu \tilde{\tau}_1$ are open. Then $\tilde{\tau}_1$ is the sole NLSP, with all other MSSM supersymmetric particles having kinematically allowed decays into it. This is called the “stau NLSP” scenario.

In any case, a st lepton NLSP can decay like $\tilde{\ell} \to \ell \tilde{G}$ according to eq. (6.32), with a width and decay length just given by eqs. (8.9) and (8.10) with the replacements $\kappa_{1\gamma} \to 1$ and $m_{\tilde{N}_1} \to m_\ell$. So, as for the neutralino NLSP case, the decay $\tilde{\ell} \to \ell \tilde{G}$ can be either fast or very slow, depending on the scale of supersymmetry breaking.

If $\sqrt{(F)}$ is larger than roughly $10^3$ TeV (or the gravitino is heavier than a keV or so), then the NLSP is so long-lived that it will usually escape a typical collider detector. If $\tilde{N}_1$ is the NLSP, then, it might as well be the LSP from the point of view of collider physics. However, the decay of $\tilde{N}_1$ into the gravitino is still important for cosmology, since an unstable $\tilde{N}_1$ is clearly not a good dark matter candidate while the gravitino LSP conceivably could be. On the other hand, if the NLSP is a long-lived charged slepton, then one can see its tracks (or possibly decay kinks) inside a collider detector [127]. The presence of a massive charged NLSP can be established by measuring an anomalously long time-of-flight or high ionization rate for a track in the detector.
9 Experimental signals for supersymmetry

So far, the experimental study of supersymmetry has unfortunately been confined to setting limits. As we have already remarked in section 5.4, there can be indirect signals for supersymmetry from processes that are rare or forbidden in the Standard Model but have contributions from sparticle loops. These include $\mu \to e\gamma$, $b \to s\gamma$, neutral meson mixing, electric dipole moments for the neutron and the electron, etc. There are also virtual sparticle effects on Standard Model predictions like $R_b$ (the fraction of hadronic $Z$ decays with $b\bar{b}$ pairs) [202] and the anomalous magnetic moment of the muon [203], which already exclude some otherwise viable models. Extensions of the MSSM (GUT and otherwise) can quite easily predict proton decay and neutron-antineutron oscillations at low but observable rates, even if $R$-parity is exactly conserved. However, it would be impossible to ascribe a positive result for any of these processes to supersymmetry in an unambiguous way. There is no substitute for the direct detection of sparticles and verification of their quantum numbers and interactions. In this section we will give an incomplete and qualitative review of some of the possible signals for direct detection of supersymmetry. The reader is encouraged to consult references below for reviews that cover the subject more systematically.

9.1 Signals at hadron colliders

The effort to discovery supersymmetry should come to fruition at hadron colliders operating in the present and near future. At this writing, the CDF and DØ detectors at the Fermilab Tevatron $p\bar{p}$ collider with $\sqrt{s} = 1.96$ TeV are looking for evidence of sparticles and Higgs bosons. Within the next few years, the CERN Large Hadron Collider (LHC) will continue this search at $\sqrt{s} = 14$ TeV. If supersymmetry is the solution to the hierarchy problem discussed in the Introduction, then the Tevatron may [201], and the LHC almost certainly will [205]-[209], find direct evidence for it.

At hadron colliders, sparticles can be produced in pairs from parton collisions of electroweak strength:

\begin{align*}
q\bar{q} &\rightarrow \tilde{C}_i^+ \tilde{C}_j^-, \tilde{N}_i\tilde{N}_j, & u\bar{d} &\rightarrow \tilde{C}_i^+ \tilde{N}_j, & d\bar{u} &\rightarrow \tilde{C}_i^- \tilde{N}_j, \\
q\bar{q} &\rightarrow \tilde{\ell}_i^+ \tilde{\ell}_j^-, \tilde{\nu}_L\tilde{\nu}_R^*, & u\bar{d} &\rightarrow \tilde{\ell}_L^+ \tilde{\nu}_L^*, & d\bar{u} &\rightarrow \tilde{\ell}_L^- \tilde{\nu}_R^*,
\end{align*}

as shown in fig. 9.1, and reactions of QCD strength:

\begin{align*}
\gg &\rightarrow \tilde{g}\tilde{g}, & \tilde{q}\tilde{q}^*, \\
\gg &\rightarrow \tilde{g}\tilde{q}_i, \\
\gq &\rightarrow \tilde{g}\tilde{g}, & \tilde{q}\tilde{q}^*, \\
\qq &\rightarrow \tilde{q}\tilde{q}_j,
\end{align*}

as shown in figs. 9.2 and 9.3. The reactions in (9.1) and (9.2) get contributions from electroweak vector bosons in the $s$-channel, and those in (9.1) also have $t$-channel squark-exchange contributions that are of lesser importance in most models. The processes in (9.3)-(9.6) get contributions from the $t$-channel exchange of an appropriate squark or gluino, and (9.3) and (9.5) also have gluon $s$-channel contributions. In a crude first approximation, for the hard parton collisions needed to make heavy particles, one may think of the Tevatron as a quark-antiquark collider, and the LHC as a gluon-gluon and gluon-quark collider. However, the signals are always an inclusive combination of the results of parton collisions of all types, and often cannot be neatly separated.

At the Tevatron collider, the chargino and neutralino production processes (mediated primarily by valence quark annihilation into virtual weak bosons) tend to have the larger cross-sections, unless the squarks or gluino are rather light (less than 300 GeV or so). In a typical model where $\tilde{C}_1$ and $\tilde{N}_2$ are mostly $SU(2)_L$ gauginos and $\tilde{N}_1$ is mostly bino, the largest production cross-sections in (9.1) are...
Figure 9.1: Feynman diagrams for electroweak production of sparticles at hadron colliders from quark-antiquark annihilation. The charginos and neutralinos in the $t$-channel diagrams only couple because of their gaugino content, for massless initial-state quarks, and so are drawn as wavy lines superimposed on solid.

Figure 9.2: Feynman diagrams for gluino and squark production at hadron colliders from gluon-gluon and gluon-quark fusion.
belong to the $\tilde{C}_1^+ \tilde{C}_1^-$ and $\tilde{C}_1 \tilde{N}_2$ channels, because they have significant couplings to $\gamma$, $Z$ and $W$ bosons, respectively, and because of kinematics. At the LHC, the situation is typically reversed, with production of gluinos and squarks by gluon-gluon and gluon-quark fusion usually dominating, unless the gluino and squarks are heavier than 1 TeV or so. At both colliders, one can also have associated production of a chargino or neutralino together with a squark or gluino, but most models predict that the cross-sections (of mixed electroweak and QCD strength) are much lower than for the ones in (9.1)-(9.6). Slepton pair production as in (9.2) may be rather small at the Tevatron, but might be observable there or at the LHC \[210\]. Cross-sections for sparticle production at hadron colliders can be found in refs. \[211\], and have been incorporated in computer programs including \[186\], \[212\]-\[217\].

The decays of the produced sparticles result in final states with two neutralino LSPs, which escape the detector. The LSPs carry away at least $2m_{\tilde{N}_1}$ of missing energy, but at hadron colliders only the component of the missing energy that is manifest in momenta transverse to the colliding beams (denoted $E_T$) is observable. So, in general the observable signals for supersymmetry at hadron colliders are $n$ leptons + $m$ jets + $E_T$, where either $n$ or $m$ might be 0. There are important Standard Model backgrounds to many of these signals, especially from processes involving production of $W$ and $Z$ bosons that decay to neutrinos, which provide the $E_T$. Therefore it is important to identify specific signals for which the backgrounds can be reduced. Of course, this depends on which sparticles are being produced and how they decay.

The classic $E_T$ signal for supersymmetry at hadron colliders is events with jets and $E_T$ but no energetic isolated leptons. The latter requirement reduces backgrounds from Standard Model processes with leptonic $W$ decays, and is obviously most effective if the relevant sparticle decays have sizable branching fractions into channels with no leptons in the final state. One must choose the $E_T$ cut high enough to reduce backgrounds from detector mismeasurements of jet energies. The jets+$E_T$ signature is one of the main signals currently being searched for at the Tevatron, and is also a favorite possibility for the first evidence for supersymmetry to be found at the LHC. It can get contributions from every type of sparticle pair production, except sleptons.

The trilepton signal \[218\] is another possible discovery mode, featuring three leptons plus $E_T$, and possibly hadronic jets. At the Tevatron, this would most likely come about from electroweak $\tilde{C}_1 \tilde{N}_2$ production followed by the decays indicated in eq. (8.4), in which case high-$p_T$ hadronic activity should be absent in the event. A typical Feynman diagram for such an event is shown in fig. 9.4. It could
Figure 9.4: A complete Feynman diagram for a clean (no high-\(p_T\) hadronic jets) trilepton event at a hadron collider, from production of an on-shell neutralino and a chargino, with subsequent leptonic decays, leading in this case to \(\mu^+\mu^-e^+ + E_T\).

also come from \(\bar{g}g\), \(qg\), or \(\bar{q}g\) production, with one of the gluinos or squarks decaying through a \(\tilde{C}_1\) and the other through a \(\tilde{N}_2\). This is the more likely origin at the LHC. In that case, there will be very high-\(p_T\) jets from the decays, in addition to the three leptons and \(E_T\). These signatures rely on the \(\tilde{N}_2\) having a significant branching fraction for the three-body decay to leptons in eq. (8.4). The competing two-body decay modes \(\tilde{N}_2 \rightarrow h^0 \tilde{N}_1\) and \(\tilde{N}_2 \rightarrow Z \tilde{N}_1\) are sometimes called “spoiler” modes, since if they are kinematically allowed they can dominate, spoiling the trilepton signal, especially at the Tevatron. This is because if the \(\tilde{N}_2\) decay is through an on-shell \(h^0\), then the final state will very likely include bottom-quark jets rather than isolated leptons, while if the decay is through an on-shell \(Z\), then there can still be two leptons but there are Standard Model backgrounds with unfortunately similar kinematics from processes involving \(Z \rightarrow \ell^+\ell^-\). Although the trilepton signal is lost, other leptons + jets + \(E_T\) signals may be observable above Standard Model backgrounds, especially if bottom quark jets can be tagged with high efficiency. In fact, supersymmetric events with \(h^0 \rightarrow b\bar{b}\) following from \(\tilde{N}_2 \rightarrow h^0 \tilde{N}_1\) could be the easiest way to discover \(h^0\) at the LHC.

Another possibility with controllable backgrounds, the same-charge dilepton signal [219], can occur if the gluino decays with a significant branching fraction to hadrons plus a chargino, which can subsequently decay into a final state with a charged lepton, a neutrino, and \(\tilde{N}_1\). Since the gluino doesn’t know anything about electric charge, the single charged lepton produced from each gluino decay can have either sign with equal probability, as discussed in section 8.4. This means that gluino pair production or gluino-squark production will often lead to events with two leptons with the same charge (but possibly different flavors) plus jets and \(E_T\). This signal can also arise from squark pair production, for example if the squarks decay like \(\tilde{q} \rightarrow q\tilde{g}\). The same-charge dilepton signal has small physics backgrounds from the Standard Model both at the Tevatron and the LHC. The reason is that the largest background sources for isolated lepton pairs, namely \(W^+W^-,\) Drell-Yan and \(t\bar{t}\) production, can only yield opposite-charge dileptons.

Despite the backgrounds just mentioned, opposite-charge dilepton signals, for example from slepton pair production with subsequent decays \(\tilde{\ell} \rightarrow \ell\tilde{N}_1\), can also give an observable signal, especially at the LHC. Another important possibility for the LHC, but probably not the Tevatron, is the single lepton plus jets plus \(E_T\) signal [205]. It has large Standard Model backgrounds from processes with \(W \rightarrow \ell\nu\). However, at the LHC it also can have an extremely large rate from various sparticle production modes, and may give the best discovery signal. One should also be aware of interesting signals that can appear for particular ranges of parameters. For example, in a model studied in ref. [220], the only two-body decay channel for the gluino is \(\tilde{g} \rightarrow b\bar{b}_1\), with subsequent decays \(\bar{b}_1 \rightarrow b\tilde{N}_2\) and \(\tilde{N}_2 \rightarrow \ell^+\ell^-\tilde{N}_1\) or \(\tilde{N}_2 \rightarrow q\bar{q}\tilde{N}_1\). In that case, gluino pair production gives a spectacular signal of four bottom jets plus up to four leptons plus \(E_T\). In general, production of relatively light \(\tilde{t}_1\) and \(\tilde{b}_1\) can give hadron collider signals rich in bottom jets, either through direct production or cascade decays.

After the evidence for the existence of supersymmetry is acquired, the LHC data can be used to measure sparticle masses by analyzing the kinematics of the decays. With a neutralino LSP always
escaping the detector, there are no true invariant mass peaks possible. However, various combinations of masses can be measured using kinematic edges and other reconstruction techniques. For example, if the decay of the second-lightest neutralino occurs in two stages through a real slepton, \( \tilde{N}_2 \rightarrow \ell \ell \rightarrow \ell^+ \ell^- \tilde{N}_1 \), then the resulting dilepton invariant mass distribution is as shown in fig. 9.5. It features a sharp edge, allowing a precision measurement of the corresponding combination of \( N_2, \tilde{\ell}, \) and \( \tilde{N}_1 \) masses \[221, 222, 206\]. There are significant backgrounds to this analysis, for example coming from \( t\bar{t} \) production. However, since the signal from \( \tilde{N}_2 \) has same-flavor leptons, while the background has contributions from different flavors. Therefore the edge can be enhanced by plotting the combination \([e^+e^-] + [\mu^+\mu^-] - [e^+\mu^-] - [\mu^+e^-] \), subtracting the background.

Heavier sparticle mass combinations can also be reconstructed at the LHC \[206, 208\], \[223\]-\[228\] using other kinematic distributions. For example, consider the gluino decay chain \( \tilde{g} \rightarrow q\bar{q}' \rightarrow q\bar{q}\tilde{N}_2 \) with \( \tilde{N}_2 \rightarrow \ell \ell' \rightarrow \ell^+ \ell^- \tilde{N}_1 \) as above. By selecting events close to the dilepton mass edge as determined in the previous paragraph, one can reconstruct a peak in the invariant mass of the \( jj \ell^+ \ell^- \) system, which correlates well with the gluino mass. As another example, the decay \( \tilde{q}_L \rightarrow q\tilde{N}_2 \) with \( \tilde{N}_2 \rightarrow h^0\tilde{N}_1 \) can be analyzed by selecting events near the peak from \( h^0 \rightarrow b\bar{b} \). There will then be a broad \( jjb\bar{b} \) invariant mass distribution, with a maximum value that can be related to \( m_{\tilde{N}_2}, m_{\tilde{N}_1}, \) and \( m_{\tilde{q}_L} \), if \( m_{h^0} \) is known. There are many other similar opportunities, depending on the specific sparticle spectrum. These techniques generally will determine the sparticle mass differences much more accurately than the individual masses; the mass of the unobserved LSP will be constrained but not precisely measured.

In all of the signals listed above, the final state leptons might be predominantly tau, and so a significant fraction will be realized as hadronic \( \tau \) jets. This is because most models predict that \( \tau_1 \) is lighter than the selectrons and smuons. Similarly, supersymmetric events may have a preference for bottom jets, sometimes through decays involving top quarks because \( \tilde{t}_1 \) is relatively light, and sometimes because \( b_1 \) is expected to be lighter than the squarks of the first two families, and sometimes for both reasons. Other things being equal, the larger \( \tan \beta \) is, the stronger the preference for hadronic \( \tau \) and b jets will be in supersymmetric events.

The Higgs scalar bosons of the MSSM are also the target of searches at the Tevatron and the LHC. At the Tevatron, the searches for \( h^0 \) (see \[229\] and references in it) in most cases have the same signatures as for the Standard Model Higgs boson, but perhaps different rates. They include:

\[
\begin{align*}
q\bar{q} & \rightarrow Zh^0 \rightarrow \nu\bar{\nu}bb \\
q\bar{q} & \rightarrow Wh^0 \rightarrow \ell\nu bb \\
q\bar{q} & \rightarrow Wh^0 \rightarrow WWW^{(*)} \\
gg & \rightarrow h^0 \rightarrow WWW^{(*)} \rightarrow \ell^+\ell^-\nu\bar{\nu}
\end{align*}
\]

The largest cross-section for Higgs production is expected to be from the one-loop gluon fusion process \( gg \rightarrow h^0 \), mediated by one-loop diagrams with \( t, b, \bar{t}_{1,2}, \bar{b}_{1,2} \) circulating in the loop, but the corresponding backgrounds are also immense. At present, the discovery prospects for all of these searches seem to be quite limited by luminosity. Other Tevatron searches take advantage of possible enhancements of the MSSM Higgs couplings to bottom quarks and tau leptons compared to the Standard Model ones. These include looking for \( p\bar{p} \rightarrow \phi^0 + X \) (including contributions from gluon fusion and radiation from
bottom quark lines) where \( \phi^0 = h^0, H^0, A^0 \), followed by \( \phi^0 \to \tau^+ \tau^- \). This searches will have some reach only when \( \tan \beta \) is large and \( m_{A^0} \) is not far above \( m_Z \). There is also a search for the charged Higgs boson appearing in top decays, \( t \to bH^+ \) (which must compete with the Standard Model top-quark decay), followed by \( H^+ \to \tau^+ \nu_\tau \). Detailed information on these searches can be found in [229].

At the LHC, studies indicate (see for example [230]-[233]) that at least one of the MSSM Higgs scalar bosons is very likely to be discovered throughout the parameter space, at least in the limit of no new CP violation in the supersymmetry-breaking couplings. The process \( gg \to h^0 \) has a very large cross-section and so can lead to discovery through the decays:

\[
\begin{align*}
    h^0 &\to \gamma\gamma \\
    h^0 &\to ZZ^{(*)} \to \ell^+ \ell^- \ell'^+ \ell'^- \\
    h^0 &\to WW^{(*)} \to \ell^+ \nu \ell'^- \bar{\nu}.
\end{align*}
\] (9.11)

The decay to photons is again a one-loop process, and therefore rare, but the backgrounds can be measured from the data away from the Higgs peak. Both the \( \gamma\gamma \) and \( ZZ^{(*)} \) may allow precision determinations of the mass, at the per cent level or better. Another possible LHC discovery mode comes from electroweak vector boson fusion, \( W^+ W^- \to h^0 \) and \( ZZ \to h^0 \). Here the \( W \) and \( Z \) bosons are radiated off of the initial-state quark lines, leaving two very forward jets, which can be used as tags for the process. So the signature is

\[
pp \to h^0 jj \to \tau^+ \tau^- jj \text{ or } WW^{(*)} jj
\] (9.14)

where the light flavor jets \( j \) are forward, and the \( h^0 \) decay products are required to be in the central region of the detector. The large top Yukawa coupling together with the high LHC energy also allows a possible signal from radiating off of a top-quark line:

\[
pp \to t\bar{t}h^0 \to t\bar{t}bb.
\] (9.15)

The signatures mentioned in the previous paragraph are also found in the Standard Model. The special features of supersymmetry allow more discovery signals, including radiation of \( h^0 \) off of a bottom-quark line:

\[
pp \to b\bar{b}h^0 \to b\bar{b} \mu^+ \mu^-
\] (9.16)

relying on a possible enhancement of the coupling of \( h^0 \) to both bottom quarks and muons, compared to the Standard Model. The heavier neutral Higgs scalars can also be searched for in decays

\[
\begin{align*}
    A^0/H^0 &\to \tau^+ \tau^- , \, \mu^+ \mu^- , \, b\bar{b} , \, t\bar{t}, \\
    H^0 &\to h^0 h^0, \\
    A^0 &\to Z h^0 \to \ell^+ \ell^- b\bar{b},
\end{align*}
\] (9.17-19)

with prospects that vary considerably depending on the parameters of the model. The charged Higgs boson may also appear at the LHC in top-quark decays, as mentioned above for the Tevatron, if \( m_{H^+} < m_t \). If instead \( m_{H^+} > m_t \), then one can look for

\[
bg \to tH^-, \quad gg \to t\bar{t}H^-.
\] (9.20)

followed by the decay \( H^- \to \tau^- \nu_\tau \) in each case. More details on the prospects for Higgs scalar discovery at the LHC can be found in [230]-[233].

The rest of this subsection briefly considers the possibility that the LSP is the goldstino/gravitino, in which case the sparticle discovery signals discussed above can be significantly improved. If the
NLSP is a neutralino with a prompt decay, then $\tilde{N}_1 \rightarrow \gamma G$ will yield events with two energetic, isolated photons plus $E_T$ from the escaping gravitinos, rather than just $E_T$. So at a hadron collider the signal is $\gamma\gamma + X + E_T$ where $X$ is any collection of leptons plus jets. The Standard Model backgrounds relevant for such events are quite small. If the $\tilde{N}_1$ decay length is long enough, then it may be measurable because the photons will not point back to the event vertex. This would be particularly useful, as it would give an indication of the supersymmetry-breaking scale $\sqrt{F}$; see eq. (6.32) and the discussion in subsection 8.5. If the $\tilde{N}_1$ decay is outside of the detector, then one just has the usual leptons + jets + $E_T$ signals as discussed above in the neutralino LSP scenario.

In the case that the NLSP is a charged slepton, then the decay $\tilde{\ell} \rightarrow \ell G$ can provide two extra leptons in each event, compared to the signals with a neutralino LSP. If the $\tilde{\tau}_1$ is sufficiently lighter than the other charged sleptons $\tilde{\ell}_R$, $\tilde{\mu}_R$ and so is effectively the sole NLSP, then events will always have a pair of taus. If the slepton NLSP is long-lived, one can look for events with a pair of very heavy charged particle tracks or a long time-of-flight in the detector. Since slepton pair production usually has a much smaller cross-section than the other processes in (9.1)-(9.6), this will typically be accompanied by leptons and/or jets from the same event vertex, which may be of crucial help in identifying candidate events. It is also quite possible that the decay length of $\tilde{\ell} \rightarrow \ell G$ is measurable within the detector, seen as a macroscopic kink in the charged particle track. This would again be a way to measure the scale of supersymmetry breaking through eq. (6.32).

**9.2 Signals at $e^+e^-$ colliders**

At $e^+e^-$ colliders, all sparticles (except the gluino) can be produced in tree-level reactions:

$$e^+e^- \rightarrow \tilde{C}_i^+ \tilde{C}_j^-, \tilde{N}_i\tilde{N}_j, \tilde{\ell}^+\tilde{\ell}^-, \tilde{\nu}\tilde{\nu}^*, \tilde{q}\tilde{q}^*,$$

as shown in figs. 9.6, 9.10. The important interactions for sparticle production are just the gaugino-fermion-scalar couplings shown in Figures 5.3, c and the ordinary vector boson interactions. The cross-sections are therefore determined just by the electroweak gauge couplings and the sparticle mixings. They were calculated in ref. [197], and are available in computer programs [186], [212]-[215], [234].

All of the processes in eq. (9.21) get contributions from the s-channel exchange of the $Z$ boson and, for charged sparticle pairs, the photon. In the cases of $\tilde{C}_i^+\tilde{C}_j^-$, $\tilde{U}_i\tilde{U}_j$, $\tilde{E}_i^\pm\tilde{E}_j^\mp$, $\tilde{\nu}_i\tilde{\nu}_j^*$ and $\tilde{q}\tilde{q}^*$ production, there are also $t$-channel diagrams exchanging a virtual sneutrino, selectron, neutralino, neutralino, neutralino, and chargino, respectively. The $t$-channel contributions are significant if the exchanged sparticle is not too heavy. For example, the production of wino-like $\tilde{C}_1^+\tilde{C}_1^-$ pairs typically suffers a destructive interference between the s-channel graphs with $\gamma, Z$ exchange and the t-channel graphs with $\tilde{\nu}_e$ exchange, if the sneutrino is not too heavy. In the case of sleptons, the pair production of smuons and staus proceeds only through s-channel diagrams, while selectron production also has a contribution from the t-channel exchanges of the neutralinos, as shown in Figure 9.8. For this reason, selectron production may be significantly larger than smuon or stau production at $e^+e^-$ colliders.

The pair-produced sparticles decay as discussed in section 8. If the LSP is the lightest neutralino, it will always escape the detector because it has no strong or electromagnetic interactions. Every event will have two LSPs leaving the detector, so there will be at least $2m_{\tilde{N}_1}$ of missing energy ($E_T$). For example, in the case of $\tilde{C}_1^+\tilde{C}_1^-$ production, the possible signals include a pair of acollinear leptons and $E_T$, or one lepton and a pair of jets plus $E_T$, or multiple jets plus $E_T$. The relative importance of these signals depends on the branching fraction of the chargino into the competing final states, $\tilde{C}_1 \rightarrow \tilde{\nu}_e\tilde{N}_1$ and $\tilde{q}\tilde{q'}\tilde{N}_1$. In the case of slepton pair production, the signal should be two energetic, acollinear, same-flavor leptons plus $E_T$. There is a potentially large Standard Model background for the acollinear leptons plus $E_T$ and the lepton plus jets plus $E_T$ signals, coming from $W^+W^-$ production with one or both of the $W$ bosons decaying leptonically. However, these and other Standard Model backgrounds can be kept under control with angular cuts, and beam polarization if available. It is not difficult to

construct the other possible signatures for sparticle pairs, which can become quite complicated for the heavier charginos, neutralinos and squarks.

The MSSM neutral Higgs bosons can also be produced at $e^+e^-$ colliders, with the principal processes of interest at low energies

$$e^+e^- \rightarrow h^0 Z, \quad e^+e^- \rightarrow h^0 A^0,$$

shown in fig. 9.11. At tree-level, the first of these has a cross-section given by the corresponding Standard Model cross-section multiplied by a factor of $\sin^2(\beta - \alpha)$, which approaches 1 in the decoupling limit of $m_{A^0} \gg m_Z$ discussed in section 7.1. The other process is complementary, since (up to kinematic factors) its cross-section is the same but multiplied by $\cos^2(\beta - \alpha)$, which is significant if $m_{A^0}$ is not large. If $\sqrt{s}$ is high enough [note the mass relation eq. (7.21)], one can also have

$$e^+e^- \rightarrow H^+H^-,$$

with a cross-section that is fixed, at tree-level, in terms of $m_{H^\pm}$, and

$$e^+e^- \rightarrow H^0 Z, \quad e^+e^- \rightarrow H^0 A^0,$$

with cross-sections proportional to $\cos^2(\beta - \alpha)$ and $\sin^2(\beta - \alpha)$ respectively. Also, at sufficiently high $\sqrt{s}$, the process

$$e^+e^- \rightarrow \nu_\ell \bar{\nu}_\ell h^0$$

following from $W^+W^-$ fusion provides the best way to study the Higgs boson decays, which can differ substantially from those in the Standard Model\[165\ [166].

The CERN LEP $e^+e^-$ collider conducted searches until November 2000, with various center of mass energies up to 209 GeV, yielding no firm evidence for sparticle or Higgs production. The resulting limits\[235] on the charged sparticle masses are of order roughly half of the beam energy, minus taxes paid for detection and identification efficiencies, backgrounds, and the suppression of cross-sections near threshold. The bounds become weaker if the mass difference between the sparticle in question and the LSP (or another sparticle that the produced one decays into) is less than a few GeV, because then the available visible energy can be too small for efficient detection and identification.

For example, LEP established limits $m_{\tilde{\ell}_R} > 99$ GeV and $m_{\tilde{\nu}_R} > 95$ GeV at 95% CL, provided that $m_{\tilde{\ell}_R} - m_{\tilde{\nu}_1} > 10$ GeV, and that the branching fraction for $\ell_R \rightarrow \ell \tilde{N}_1$ is 100% in each case. The limit for staus is weaker, and depends somewhat more strongly on the neutralino LSP mass.

The LEP chargino mass bound is approximately $m_{\tilde{C}_1} < 103$ GeV for mass differences $m_{\tilde{C}_1} - m_{\tilde{N}_1} > 3$ GeV, assuming that the chargino decays predominantly through a virtual $W_\pm$ or with similar branching fractions. However, this bound reduces to about $m_{\tilde{C}_1} < 92$ GeV for 100 MeV $< m_{\tilde{C}_1} - m_{\tilde{N}_1} < 3$ GeV. For small positive mass differences $0 < m_{\tilde{C}_1} - m_{\tilde{N}_1} < 100$ MeV, the limit is again about $m_{\tilde{C}_1} < 103$ GeV, because the chargino is long-lived enough to have a displaced decay vertex or leave a track as it moves through the detector. These limits assume that the sneutrino is heavier than about 200 GeV, so that it does not significantly reduce the production cross-section by interference of the $s$- and $t$-channel diagrams in fig. 9.6. If the sneutrino lighter, then the bound reduces, especially if $m_{\tilde{C}_1} - m_{\tilde{\nu}}$ is positive but small, so that the decay $\tilde{C}_1 \rightarrow \tilde{\nu}_\ell \ell$ dominates but releases very little visible energy. More details on these and many other limits from the LEP runs can be found at\[235] and\[236].

The LEP runs also have put a lower mass limit of 114 GeV on a Standard Model Higgs boson. If the MSSM parameter space is close to the decoupling limit $m_{A^0} \gg m_Z$, this bound is valid also for $h^0$. However, the bound can be weakened considerably if the decoupling limit is badly violated, to about $m_{h^0} < 92$ GeV if there is no new CP violation in the soft supersymmetry breaking Lagrangian\[237], and it is weakened further if the MSSM is extended to include new singlet Higgs and higgsino states.
Figure 9.12: The theoretical shape of the lepton energy distribution from events with $e^+e^- \rightarrow \ell^+\ell^- \rightarrow \ell^+\ell^-\tilde{N}_1\tilde{N}_1$ at a future linear collider. No cuts or initial state radiation or beamstrahlung or detector effects are included. The endpoints are $E_{\text{max/min}} = \sqrt{2}(1-m_{\tilde{N}_1}^2/m_{\ell}^2)[1 \pm (1-4m_{\ell}^2/s)^{1/2}]$, allowing precision reconstruction of both $\tilde{\ell}$ and $\tilde{N}_1$ masses.

If supersymmetry is the solution to the hierarchy problem, then the LHC should be able to establish strong evidence for it, and probably measure some of the sparticle mass differences, as discussed in the previous subsection. However, many important questions will remain. Various competing theories can also produce missing energy signatures. The overall mass scale of sparticles may not be known as well as one might like. Sparticle production will be inclusive and overlapping and might be difficult to disentangle. A future linear $e^+e^-$ collider with $\sqrt{s} \geq 500$ GeV [238, 232] should be able to resolve these issues, and establish more firmly that supersymmetry is indeed responsible, to the exclusion of other ideas. In particular, the couplings, spins, gauge quantum numbers, and absolute masses of the sparticles will all be measurable.

At a linear collider, the processes in eq. (9.21) can all be probed close to their kinematic limits, given sufficient integrated luminosity. (In the case of sneutrino pair production, this assumes that some of the decays are visible, rather than just $\tilde{\nu} \rightarrow \nu \tilde{N}_1$.) Establishing the properties of the particles can be done by making use of polarized beams and the relatively clean $e^+e^-$ collider environment. For example, consider the production and decay of sleptons in $e^+e^- \rightarrow \tilde{\ell}^+\tilde{\ell}^-$ with $\tilde{\ell} \rightarrow \ell\tilde{N}_1$. The resulting leptons will have (up to significant but calculable effects of initial-state radiation, beamstrahlung, cuts, and detector efficiencies and resolutions) a flat energy distribution as shown in fig. 9.12. By measuring the endpoints of this distribution, one can precisely and uniquely determine both $m_{\tilde{\ell}}$ and $m_{\tilde{N}_1}$. There is a large $W^+W^- \rightarrow \ell^+\ell^-\nu\bar{\nu}$ background, but this can be brought under control using angular cuts, since the positively (negatively) charged leptons from the background tend to go preferentially along the same direction as the positron (electron) beam. Also, since the background has uncorrelated lepton flavors, it can be subtracted. Changing the polarization of the electron beam will even further reduce the background, and will also allow controlled variation of the production of right-handed and left-handed sleptons, to get at the electroweak quantum numbers.

More generally, inclusive sparticle production at a given fixed $e^+e^-$ collision energy will result in a superposition of various sharp kinematic edges in lepton and jet energies, and distinctive distributions in dilepton and dijet energies and invariant masses. By varying the beam polarization and changing the beam energy, these observables give information about the couplings and masses of the sparticles. For example, in the ideal limit of a right-handed polarized electron beam, the reaction

$$e_R^-e^+ \rightarrow \tilde{C}_1^+\tilde{C}_1^- \quad (9.26)$$

is suppressed if $\tilde{C}_1$ is pure wino, because in the first diagram of fig. 9.6, the right-handed electron only couples to the $\mathbb{U}(1)_Y$ gauge boson linear combination of $\gamma, Z$ while the wino only couples to the orthogonal $SU(2)_L$ gauge boson linear combination, and in the second diagram the electron-sneutrino-chargino coupling involves purely left-handed electrons. So, the polarized beam cross-section can be used to determine the charged wino mixing with the charged Higgsino. Even more precise information about the sparticle masses can be obtained by varying the beam energy in small discrete steps very close to thresholds, an option without rival at hadron colliders. The rise of the production cross-section above threshold provides information about the spin and “handedness”, because the production cross-sections for $\tilde{\ell}_R^+\tilde{\ell}_R^-$ and $\tilde{\ell}_L^+\tilde{\ell}_L^-$ are p-wave and therefore rise like $\beta^3$ above threshold, where $\beta$ is the velocity of one of the produced sparticles. In contrast, the rates for $\tilde{e}_L^+\tilde{e}_R^-$ and for chargino and neutralino pair
production are s-wave, and therefore should rise like $\beta$ just above threshold. By measuring the angular distributions of the final state leptons and jets with respect to the beam axis, the spins of the sparticles can be inferred. These will provide crucial tests that the new physics that has been discovered is indeed supersymmetry.

A sample of the many detailed studies along these lines can be found in refs. [238]-[242]. In general, a future $e^+e^-$ collider will provide an excellent way of testing softly-broken supersymmetry and measuring the model parameters, if it has enough energy. Furthermore, the processes $e^+e^- \rightarrow h^0Z$, $h^0A^0$, $H^0Z$, $H^0A^0$, $H^+H^-$, and $h^0\ell\bar{\nu}_\ell\ell$ should be able to definitively test the Higgs sector of supersymmetry at a linear collider.

The situation may be qualitatively better if the gravitino is the LSP as in gauge-mediated models, because of the decays mentioned in section 8.5. If the lightest neutralino is the NLSP and the decay $\tilde{N}_1 \rightarrow \gamma G$ occurs within the detector, then even the process $e^+e^- \rightarrow \tilde{N}_1\tilde{N}_1$ leads to a dramatic signal of two energetic photons plus missing energy $[126]-[128]$. There are significant backgrounds to the $\gamma \gamma$ signal, but they are easily removed by cuts. Each of the other sparticle pair-production modes eq. (9.21) will lead to the same signals as in the neutralino LSP case, but now with two additional energetic photons, which should make the experimentalists’ tasks quite easy. If the decay length for $\tilde{N}_1 \rightarrow \gamma G$ is much larger than the size of a detector, then the signals revert back to those found in the neutralino LSP scenario. In an intermediate regime for the $\tilde{N}_1 \rightarrow \gamma G$ decay length, one may see events with one or both photons displaced from the event vertex by a macroscopic distance.

If the NLSP is a charged slepton $\tilde{\ell}$, then $e^+e^- \rightarrow \tilde{\ell}\bar{\ell}$ followed by prompt decays $\tilde{\ell} \rightarrow \ell\tilde{G}$ will yield two energetic same-flavor leptons in every event, and with a different energy distribution than the acollinear leptons that would follow from either $\tilde{C}_1^+\tilde{C}_1^-$ or $\tilde{\ell}\bar{\ell}$ production in the neutralino LSP scenario. Pair production of non-NLSP sparticles will yield unmistakable signals, which are the same as those found in the neutralino NLSP case but with two additional energetic leptons (not necessarily of the same flavor). An even more striking possibility is that the NLSP is a slepton that decays very slowly $[127]$. If the slepton NLSP is so long-lived that it decays outside the detector, then slepton pair production will lead to events featuring a pair of charged particle tracks with high ionization rates that betray their very large mass. If the sleptons decay within the detector, then one can look for large-angle kinks in the charged particle tracks, or a macroscopic impact parameter. The pair production of any of the other heavy charged sparticles will also yield heavy charged particle tracks or decay kinks, plus leptons and/or jets, but no $E$ unless the decay chains happen to include neutrinos. It may also be possible to identify the presence of a heavy charged NLSP by measuring its anomalously long time-of-flight through the detector.

In both the neutralino and slepton NLSP scenarios, a measurement of the decay length to $\tilde{G}$ would provide a great opportunity to measure the supersymmetry-breaking scale $\sqrt{F}$, as discussed in subsection 8.5.

### 9.3 Dark matter and its detection

Evidence from experimental cosmology has now solidified to the point that, with some plausible assumptions, the cold dark matter density is known to be $[243]-[246]$

$$\Omega_{DM}h^2 \approx 0.11,$$

with statistical errors of order 5%, and systematic errors that are less clear. Here $\Omega_{DM}$ is the average energy density in non-baryonic dark matter divided by the total critical density that would lead to a spatially flat homogeneous universe, and $h$ is the Hubble constant in units of 100 km sec$^{-1}$ Mpc$^{-1}$, observed to be $h^2 \approx 0.5$ with an error of order 10%. This translates into a cold dark matter density

$$\rho_{DM} \approx 1.2 \times 10^{-6} \text{ GeV/cm}^3,$$
averaged over very large distance scales.

One of the nice features of supersymmetry with exact $R$-parity conservation is that a stable electrically neutral LSP might be this cold dark matter. There are three obvious candidates: the lightest sneutrino, the gravitino, and the lightest neutralino. The possibility of a sneutrino LSP making up the dark matter with a cosmologically interesting density has been largely ruled out by direct searches \[244\] (see however \[245\]). If the gravitino is the LSP, as in many gauge-mediated supersymmetry breaking models, then gravitinos from reheating after inflation \[246\] or from other sparticle decays \[247\] might be the dark matter, but they would be impossible to detect directly even if they have the right cosmological density today. They interact too weakly. The most attractive prospects for direct detection of supersymmetric dark matter, therefore, are based on the idea that the lightest neutralino $\tilde{N}_1$ is the LSP \[64, 248\].

In the early universe, sparticles existed in thermal equilibrium with the ordinary Standard Model particles. As the universe cooled and expanded, the heavier sparticles could no longer be produced, and they eventually annihilated or decayed into neutralino LSPs. Some of the LSPs pair-annihilated into final states not containing sparticles. If there are other sparticles that are only slightly heavier, then they existed in thermal equilibrium in comparable numbers to the LSP, and their co-annihilations are also important in determining the resulting dark matter density \[249, 250\]. Eventually, as the density decreased, the annihilation rate became small compared to the cosmological expansion, and the $\tilde{N}_1$ experienced “freeze out”, with a density today determined by this small rate and the subsequent dilution due to the expansion of the universe.

In order to get the observed dark matter density today, the thermal-averaged effective annihilation cross-section times the relative speed $v$ of the LSPs should be about \[248\]

$$\langle \sigma v \rangle \sim 1 \text{ pb} \sim \frac{\alpha^2}{(150 \text{ GeV})^2},$$  \hspace{1cm} (9.29)$$

so a neutralino LSP naturally has, very roughly, the correct (electroweak) interaction strength and mass. More detailed and precise estimates can be obtained with publicly available computer programs \[194, 195\], so that the predictions of specific candidate models of supersymmetry breaking can be compared to eq. \[9.29\]. Some of the diagrams that are typically important for neutralino LSP pair annihilation are shown in fig. 9.13 Depending on the mass of $\tilde{N}_1$, various other processes including $\tilde{N}_1\tilde{N}_1 \to ZZ, Zh^0, h^0h^0$ or even $W^\pm H^\mp, ZA^0, h^0A^0, h^0H^0, H^0A^0, H^0H^0, A^0A^0$, or $H^+H^-$ may also have been important. Some of the diagrams that can lead to co-annihilation of the LSPs with slightly heavier sparticles are shown in figs. 9.14 and 9.15.

If $\tilde{N}_1$ is mostly higgsino or mostly wino, then the the annihilation diagram fig. 9.13; and the co-annihilation mechanisms provided by fig. 9.14 are typically much too efficient \[251, 252, 253\] to provide the full required cold dark matter density, unless the LSP is very heavy, of order 1 TeV or more. This is often considered to be somewhat at odds with the idea that supersymmetry is the solution to the hierarchy problem. However, for lighter higgsino-like or wino-like LSPs, non-thermal mechanisms can be invoked to provide the right dark matter abundance \[159, 254\].
A recurring feature of many models of supersymmetry breaking is that the lightest neutralino is mostly bino. It turns out that in much of the parameter space not already ruled out by LEP with a bino-like $\tilde{N}_1$, the predicted relic density is too high, either because the LSP couplings are too small, or the sparticles are too heavy, or both, leading to an annihilation cross-section that is too low. To avoid this, there must be significant contributions to $\langle \sigma v \rangle$. The possibilities can be classified qualitatively in terms of the diagrams that contribute most strongly to the annihilation.

First, if at least one sfermion is not too heavy, the diagram of fig. 9.13a is effective in reducing the dark matter density. In models with a bino-like $\tilde{N}_1$, the most important such contribution usually comes from $\tilde{e}_R$, $\tilde{\mu}_R$, and $\tilde{\tau}_1$ slepton exchange. The region of parameter space where this works out right is often referred to by the jargon “bulk region”, because it corresponded to the main allowed region with dark matter density less than the critical density, before $\Omega_{\text{DM}}h^2$ was accurately known and before the highest energy LEP searches had happened. However, the diagram of fig. 9.13a is subject to a $p$-wave suppression, and so sleptons that are light enough to reduce the relic density sufficiently are, in many models, also light enough to be excluded by LEP, or correspond to light Higgs bosons that are excluded by LEP, or have difficulties with other indirect constraints. In the minimal supergravity inspired framework described in section 6.6, the remaining viable bulk region usually takes $m_0$ and $m_{1/2}$ less than about 100 GeV and 250 GeV respectively, depending on other parameters.

A second way of annihilating excess bino-like LSPs to the correct density is obtained if $2m_{\tilde{N}_1} \approx m_{A^0}$, or $m_{h^0}$, or $m_{H^0}$, as shown in fig. 9.13b, so that the cross-section is near a resonance pole. An $A^0$ resonance annihilation will be $s$-wave, and so more efficient than a $p$-wave $h^0$ or $H^0$ resonance. Therefore, the most commonly found realization involves annihilation through $A^0$. Because the $A^0\tilde{b}\tilde{b}$ coupling is proportional to $m_t \tan \beta$, this usually entails large values of $\tan \beta$ [255]. (Annihilation through $h^0$ is also possible [256].) The region of parameter space where this happens is often called the “$A$-funnel” or “Higgs funnel” or “Higgs resonance region”.

A third effective annihilation mechanism is obtained if $\tilde{N}_1$ mixes to obtain a significant higgsino or wino admixture. Then both fig. 9.13c and the co-annihilation diagrams of fig. 9.14 can be important [252]. In the “focus point” region of parameter space, where $|\mu|$ is not too large, an LSP with a significant higgsino content can yield the correct relic abundance even for very heavy squarks and sleptons [257]. (This is motivated by focusing properties of the renormalization group equations, which allow $|\mu| \ll m_0^2$ in minimal supergravity inspired models [258, 259].) It is also possible to arrange for just enough wino content in the LSP to do the job [260], by choosing $M_1/M_2$ appropriately.
A fourth possibility, the “sfermion co-annihilation region” of parameter space, is obtained if there is a sfermion that happens to be less than a few GeV heavier than the LSP \[249\]. In many model frameworks, this is most naturally the lightest stau \[261\], but it could also be the lightest top squark \[262\]. A significant density of this sfermion will then coexist with the LSP around the freeze-out time, and so annihilations involving the sfermion with itself or with the LSP, including those of the type shown in fig. 9.15 will further dilute the number of sparticles and so the eventual dark matter density.

However, it is important to keep in mind that a set of MSSM Lagrangian parameters that fails to predict the correct relic dark matter abundance by the standard thermal mechanisms is not ruled out as a model for collider physics. This is because simple extensions can completely change the relic abundance prediction without changing the predictions for colliders much or at all. For example, if the model predicts a neutralino dark matter abundance that is too small, one need only assume another sector (even a completely disconnected one) with a stable neutral particle, or that the dark matter is supplied by some non-thermal mechanism such as out-of-equilibrium decays of heavy particles. If the predicted neutralino dark matter abundance appears to be too large, one can assume that \(R\)-parity is slightly broken, so that the offending LSP decays before nucleosynthesis; this would require some other unspecified dark matter candidate. Or, the dark matter LSP might be some particle that the lightest neutralino decays into. One possibility is a gravitino LSP \[247\]. Another example is obtained by extending the model to solve the strong CP problem with an invisible axion, which can allow the LSP to be a very weakly-interacting axino \[263\] (the fermionic supersymmetric partner of the axion). In such cases, the dark matter density after the lightest neutralino decays would be reduced compared to its naively predicted value by a factor of \(m_{\text{LSP}}/m_{\tilde{N}_1}\), provided that other sources for the LSP relic density are absent. A correct density for neutralino LSPs can also be obtained by assuming that they are produced non-thermally in reheating of the universe after neutralino freeze-out but before nucleosynthesis \[264\]. Finally, in the absence of a compelling explanation for the apparent cosmological constant, it seems possible that the standard model of cosmology will still need to be modified in ways not yet imagined.

If neutralino LSPs really make up the cold dark matter, then their local mass density in our neighborhood ought to be of order 0.3 GeV/cm\(^3\) [much larger than the density averaged over the largest scales, eq. (9.28)] in order to explain the dynamics of our own galaxy. LSP neutralinos could be detectable directly through their weak interactions with ordinary matter, or indirectly by their ongoing annihilations. However, the halo is subject to significant uncertainties in overall size, velocity, and clumpiness, so even if the Lagrangian parameters were known exactly, the signal rates would be quite indefinite, possibly even by orders of magnitude.

The direct detection of \(\tilde{N}_1\) depends on their elastic scattering off of heavy nuclei in a detector. At the parton level, \(\tilde{N}_1\) can interact with a quark by virtual exchange of squarks in the s-channel, or Higgs scalars or a Z boson in the t-channel. It can also scatter off of gluons through one-loop diagrams. The scattering mediated by neutral Higgs scalars is suppressed by tiny Yukawa couplings, but is coherent for the quarks and so can actually be the dominant contribution for nuclei with larger atomic weights, if the squarks are heavy. The energy transferred to the nucleus in these elastic collisions is typically of order tens of keV per event. There are important backgrounds from natural radioactivity and cosmic rays, which can be reduced by shielding and pulse-shape analysis. A wide variety of current or future experiments are sensitive to some, but not all, of the parameter space of the MSSM that predicts a dark matter abundance in the range of eq. (9.27).

Another, more indirect, way to detect neutralino LSPs is through ongoing annihilations. This can occur in regions of space where the density is greatly enhanced. If the LSPs lose energy by repeated elastic scattering with ordinary matter, they can eventually become concentrated inside massive astronomical bodies like the Sun or the Earth. In that case, the annihilation of neutralino pairs into final states leading to neutrinos is the most important process, since no other particles can escape from the center of the object where the annihilation is going on. In particular, muon neutrinos and
antineutrinos from $\tilde{N}_1\tilde{N}_1 \rightarrow W^+W^-$ or $ZZ$, (or possibly $\tilde{N}_1\tilde{N}_1 \rightarrow \tau^+\tau^-$ or $\nu\bar{\nu}$, although these are $p$-wave suppressed) will travel large distances, and can be detected in neutrino telescopes. The neutrinos undergo a charged-current weak interaction in the earth, water, or ice under or within the detector, leading to energetic upward-going muons pointing back to the center of the Sun or Earth.

Another possibility is that neutralino LSP annihilation in the galactic center (or the halo) could result in high-energy photons from cascade decays of the heavy Standard Model particles that are produced. These photons could be detected in air Cerenkov telescopes or in space-based detectors. There are also interesting possible signatures from neutralino LSP annihilation in the galactic halo producing detectable quantities of high-energy positrons or antiprotons.

More information on these possibilities, and the various experiments that can exploit them, can be found from refs. [248] and papers referred to in them.

10 Some miscellaneous variations

In this section I will briefly outline a few favorite variations on the basic picture of the MSSM that has been outlined above. First, the possibility of $R$-parity violation is considered in section 10.1. Another obvious way to extend the MSSM is to introduce new chiral supermultiplets, corresponding to scalars and fermions that are all sufficiently heavy to have avoided discovery so far. This requires that the new chiral supermultiplets must form a real representation of the Standard Model gauge group. The simplest such possibility is that the new particles live in just one gauge-singlet chiral supermultiplet; this is discussed in section 10.2. One can also extend the MSSM by introducing new gauge interactions that are spontaneously broken at high energies. The possibilities here include GUT models like $SU(5)$ and $SO(10)$ and $E_6$, which unify the Standard Model gauge interactions, with important implications for rare processes like proton decay and $\mu \rightarrow e\gamma$. Superstring models also usually enlarge the Standard Model gauge group at high energies. One or more Abelian subgroups could survive to the TeV scale, leading to a $Z'$ massive vector boson. There is a vast literature on these possibilities, but we will concentrate instead on the implications of just adding a single $U(1)$ factor that is assumed to be spontaneously broken at energies beyond the reach of any foreseeable collider, in section 10.3.

10.1 Models with $R$-parity violation

So far it has been assumed that $R$-parity (or equivalently matter parity) is an exact symmetry of the MSSM. This assumption precludes renormalizable proton decay and predicts that the LSP should be stable, but despite these virtues $R$-parity is not inevitable. Because of the threat of proton decay, one expects that if $R$-parity is violated, then in the renormalizable Lagrangian either B-violating or L-violating couplings are allowed, but not both, as explained in section 5.2. There are also upper bounds on the individual $R$-parity violating couplings [61].

One proposal is that matter parity can be replaced by an alternative discrete symmetry that still manages to forbid proton decay at the level of the renormalizable Lagrangian. The $Z_2$ and $Z_3$ possibilities have been cataloged in ref. [265], where it was found that provided no new particles are added to the MSSM, that the discrete symmetry is family-independent, and that it can be defined at the level of the superpotential, there is only one other candidate besides matter parity. That other possibility is a $Z_3$ discrete symmetry [265], which was originally called “baryon parity” but is more appropriately referred to as “baryon triality”. The baryon triality of any particle with baryon number $B$ and weak hypercharge $Y$ is defined to be

$$Z_3^B = \exp (2\pi i [B - 2Y]/3).$$

(10.1)

This is always a cube root of unity, since $B-2Y$ is an integer for every MSSM particle. The symmetry principle to be enforced is that the product of the baryon trialities of the particles in any term in the
Lagrangian (or superpotential) must be 1. This symmetry conserves baryon number at the renormalizable level while allowing lepton number violation; in other words, it allows the superpotential terms in eq. (5.7) but forbids those in eq. (5.8). In fact, baryon triality conservation has the remarkable property that it absolutely forbids proton decay [266]. The reason for this is simply that baryon triality requires that $B$ can only be violated in multiples of 3 units (even in non-renormalizable interactions), while any kind of proton decay would have to violate $B$ by 1 unit. So it is eminently falsifiable. Similarly, baryon triality conservation predicts that experimental searches for neutron-antineutron oscillations will be negative, since they would violate baryon number by 2 units. However, baryon triality conservation does allow the LSP to decay. If one adds some new chiral supermultiplets to the MSSM (corresponding to particles that are presumably very heavy), one can concoct a variety of new candidate discrete symmetries besides matter parity and baryon triality. Some of these will allow $B$ violation in the superpotential, while forbidding the lepton number violating superpotential terms in eq. (5.7).

Another idea is that matter parity is an exact symmetry of the underlying superpotential, but it is spontaneously broken by the VEV of a scalar with $P_R = -1$. One possibility is that an MSSM sneutrino gets a VEV [267], since sneutrinos are scalars carrying $L=1$. However, there are strong bounds [268] on $SU(2)_L$-doublet sneutrino VEVs $\langle \tilde{\nu} \rangle \ll m_Z$ coming from the requirement that the corresponding neutrinos do not have large masses. It is somewhat difficult to understand why such a small VEV should occur, since the scalar potential that produces it must include soft sneutrino squared-mass terms of order $m_{soft}^2$. One can get around this by instead introducing a new gauge-singlet chiral supermultiplet with $L=-1$. The scalar component can get a large VEV, which can induce $L$-violating terms (and in general $B$-violating terms also) in the low-energy effective superpotential of the MSSM [268].

In any case, if $R$-parity is violated, then the collider searches for supersymmetry can be completely altered. The new couplings imply single-sparticle production mechanisms at colliders, besides the usual sparticle pair production processes. First, one can have $s$-channel single sfermion production. At electron-positron colliders, the $\lambda$ couplings in eq. (5.7) give rise to $e^+e^- \rightarrow \tilde{\nu}$. At the Tevatron and LHC, single sneutrino or charged slepton production, $q\bar{q} \rightarrow \tilde{\nu}$ or $\tilde{\ell}$ are mediated by $\lambda'$ couplings, and single squark production $qq \rightarrow \tilde{q}$ is mediated by $\lambda''$ couplings in eq. (5.8). At the HERA $ep$ collider, if $\lambda'$ couplings are present, squarks are essentially scalar leptoquarks, and can be produced in the $s$-channel through $e^+q \rightarrow \tilde{q}$. Second, one can have $t$-channel exchange of sfermions, providing for gaugino production in association with a standard model fermion. At electron-positron colliders, one has $e^+e^- \rightarrow \tilde{C}\ell$ mediated by $\tilde{\nu}_\ell$ in the $t$-channel, and $e^+e^- \rightarrow \tilde{N}_1\nu$ mediated by selectrons in the $t$-channel, if the appropriate $\lambda$ couplings are present. At the Tevatron and the LHC, one can look for the partonic processes $q\bar{q} \rightarrow (\tilde{N}_1$ or $\tilde{C}$ or $\tilde{g}) + (\ell$ or $\nu$), mediated by $t$-channel squark exchange if $\lambda'$ couplings are present. If instead $\lambda''$ couplings are present, then $qq \rightarrow (\tilde{N}_1$ or $\tilde{C}$ or $\tilde{g}) + q$, again with squarks exchanged in the $t$-channel, provides a possible production mechanism.

Next consider sparticle decays. In many cases, the $R$-parity violating couplings are already constrained by experiment, or expected from more particular theoretical models, to be smaller than electroweak gauge couplings [61]. If so, then the heavier sparticles will usually decay to final states containing the LSP, as in section 8. However, now the LSP can also decay; if it is a neutralino, as most often assumed, then it will decay into three Standard Model fermions. The collider signals to be found depend on the type of $R$-parity violation.

Lepton number violating terms of the type $\lambda$ as in eq. (5.7) will lead to final states from $\tilde{N}_1$ decay with two oppositely charged, and possibly different flavor, leptons and a neutrino, as in Figure 10.1a,b. Couplings of the $\lambda'$ type will cause $\tilde{N}_1$ to decay to a pair of jets and either a charged lepton or a neutrino, as shown in Figure 10.1c,d,e. Signals with $L$-violating LSP decays will therefore always include charged leptons or large missing energy, or both.

On the other hand, if terms of the form $\lambda''$ in eq. (5.8) are present instead, then there are $B$-violating decays $\tilde{N}_1 \rightarrow qq'\ell''$ from diagrams like the one shown in Figure 10.1. In that case, supersymmetric...
events will always have lots of hadronic activity, and will only have physics missing energy signatures when the other parts of the decay chains happen to include neutrinos.

There are other possibilities, too. The decaying LSP need not be \( \tilde{N}_1 \). Sparticles that are not the LSP can, in principle, decay directly to Standard Model quarks and leptons, if the \( R \)-parity violating couplings are large enough. The \( t \)-channel exchange of sfermions can produce a pair of Standard Model fermions, leading to indirect sparticle signatures. Or, if the \( R \)-parity violating couplings are sufficiently small, then the LSP will usually decay outside of collider detectors, and the model will be difficult or impossible to distinguish from the \( R \)-parity conserving case. Complete surveys of the present experimental constraints and future prospects can be found in [61].

10.2 The next-to-minimal supersymmetric standard model

The simplest possible extension of the particle content of the MSSM is obtained by adding a new gauge-singlet chiral supermultiplet with even matter parity. The resulting model [269]-[273] is often called the next-to-minimal supersymmetric standard model or NMSSM or (M+1)SSM. The most general renormalizable superpotential for this field content is

\[
W_{\text{NMSSM}} = W_{\text{MSSM}} + \lambda SH_u H_d + \frac{1}{3} \kappa S^3 + \frac{1}{2} \mu S S^2, \tag{10.2}
\]

where \( S \) stands for both the new chiral supermultiplet and its scalar component. There could also be a term linear in \( S \) in \( W_{\text{NMSSM}} \), but in global supersymmetry it can always be removed by redefining \( S \) by a constant shift. The soft supersymmetry-breaking Lagrangian is

\[
L^\text{NMSSM}_{\text{soft}} = L^\text{MSSM}_{\text{soft}} - (a\lambda S H_u H_d - \frac{1}{3} a_\kappa S^3 + \frac{1}{2} b_S S^2 + tS + \text{c.c.}) - m_S^2 |S|^2. \tag{10.3}
\]

The tadpole coupling \( t \) could be subject to dangerous quadratic divergences in supergravity [274] unless it is highly suppressed or forbidden by some additional symmetry at very high energies.

One of the virtues of the NMSSM is that it can provide a solution to the \( \mu \) problem mentioned in sections 5.1 and 7.1. To understand this, suppose we set\(^1\) \( \mu_S = \mu = 0 \) so that there are no mass terms or dimensionful parameters in the superpotential at all, and also set the corresponding terms \( b_S = b = 0 \) and \( t = 0 \) in the supersymmetry-breaking Lagrangian. If \( \lambda, \kappa, a_\lambda \) and \( a_\kappa \) are chosen auspiciously, then phenomenologically acceptable VEVs will be induced for \( S, H_u^0 \), and \( H_d^0 \). By doing phase rotations on \( 1 \)The even more economical case with only \( t \sim m_{\text{soft}}^3 \) and \( \lambda \) and \( a_\lambda \) nonzero is also viable and interesting [273].
these fields, all three of \( s \equiv \langle S \rangle \) and \( v_u = v \sin \beta = \langle H_u^0 \rangle \) and \( v_d = v \cos \beta = \langle H_d^0 \rangle \) can be made real and positive. In this convention, \( a_\lambda + \lambda \kappa s \) and \( a_\kappa + 3\lambda \kappa v_u v_d / s \) will also be real and positive.

However, in general, this theory could have unacceptably large CP violation. This can be avoided by assuming that \( \lambda, \kappa, a_\lambda \) and \( a_\kappa \) are all real in the same convention that makes \( s, v_u \), and \( v_d \) real and positive; this is natural if the mediation mechanism for supersymmetry breaking does not introduce new CP violating phases, and is assumed in the following. To have a stable minimum with respect to variations in the scalar field phases, it is required that \( a_\lambda + \lambda \kappa s > 0 \) and \( a_\kappa (a_\lambda + \lambda \kappa s) + 3\lambda \kappa a_\lambda v_u v_d / s > 0 \). (An obvious sufficient, but not necessary, way to achieve these two conditions is to assume that \( \lambda \kappa > 0 \) and \( a_\kappa > 0 \) and \( a_\lambda > 0 \).

An effective \( \mu \)-term for \( H_u H_d \) will arise from eq. (10.5), with

\[
\mu_{\text{eff}} = \lambda s. \tag{10.4}
\]

It is determined by the dimensionless couplings and the soft terms of order \( m_s \), instead of being a free parameter conceptually independent of supersymmetry breaking. With the conventions chosen here, the sign of \( \mu_{\text{eff}} \) (or more generally its phase) is the same as that of \( \lambda \). Instead of eqs. (10.5), (10.6), the minimization conditions for the Higgs potential are now:

\[
m^2_{H_u} + \lambda^2 (s^2 + v^2 \cos^2 \beta) - (a_\lambda + \lambda \kappa s) s \cot \beta - (m_s^2 / 2) \cos (2\beta) = 0, \tag{10.5}
\]

\[
m^2_{H_d} + \lambda^2 (s^2 + v^2 \sin^2 \beta) - (a_\lambda + \lambda \kappa s) s \tan \beta + (m_s^2 / 2) \cos (2\beta) = 0, \tag{10.6}
\]

\[
m^2_S + \lambda^2 v^2 + 2\kappa^2 s^2 - a_\kappa s - (\kappa \lambda + \lambda \kappa / 2 s) v^2 \sin (2\beta) = 0. \tag{10.7}
\]

The effects of radiative corrections \( \Delta V(v_u, v_d, s) \) to the effective potential are included by replacing \( m^2_0 \to m^2 + [\partial (\Delta V) / \partial s] / 2 s \), in addition to eq. (10.5).

The absence of dimensionful terms in \( W_{\text{NMSM}} \), and the corresponding terms in \( V_{\text{NMSM}}^{\text{soft}} \), can be enforced by introducing a new symmetry. The simplest way is to notice that the new superpotential and Lagrangian will be invariant under a \( Z_3 \) discrete symmetry, under which every field in a chiral supermultiplet transforms as \( \Phi \to e^{2\pi i / 3} \Phi \), and all gauge and gaugino fields are inert. Imposing this symmetry indeed eliminates \( \mu, \mu_S, b, b_S, \) and \( t \). However, if this symmetry were exact, then because it must be spontaneously broken by the VEVs of \( S, H_u \) and \( H_d \), domain walls are expected to be produced in the electroweak symmetry breaking phase transition in the early universe [272]. These would dominate the cosmological energy density, and would cause unobserved anisotropies in the microwave background radiation. Several ways of avoiding this problem have been proposed, including late inflation after the domain walls are formed, embedding the discrete symmetry into a continuous gauged symmetry at very high energies, or allowing either higher-dimensional terms in the Lagrangian or a very small \( \mu \) term to explicitly break the discrete symmetry.

The NMSSM contains, besides the particles of the MSSM, a real \( P_R = -1 \) Weyl fermion “singlino”. These fields have no gauge couplings of their own, so they can only interact with Standard Model particles by mixing with the neutral MSSM fields with the same spin and charge. The real scalar mixes with the MSSM particles \( h^0 \) and \( H^0 \), and the pseudo-scalar mixes with \( A^0 \). One of the effects of replacing the \( \mu \) term by the dynamical field \( S \) is to raise the upper bound on the lightest Higgs mass, to:

\[
m^2_{h^0} < m^2_{Z^0} \cos^2 (2\beta) + \lambda^2 v^2 \sin^2 (2\beta) + \text{loop corrections}, \tag{10.8}
\]

where the new \( \lambda^2 \) term comes from the \( |F_3|^2 \) contribution to the potential. One can put an upper bound \( \lambda \lesssim 0.8 \) if one requires that \( \lambda \) not have a Landau pole in its RG running below the GUT mass scale. With that assumption, the lightest Higgs scalar mass must still be below about 150 GeV, provided that the particles that contribute in loops to the Higgs mass are lighter than 1 TeV or so. Also, the neutral Higgs scalars have reduced couplings to the electroweak gauge bosons, compared to
those in the Standard Model, because of the mixing with the singlets. This can make discovery more challenging and interesting.

The odd $R$-parity singlino $\tilde{S}$ mixes with the four MSSM neutralinos, so there are really five neutralinos now. The singlino could be the LSP, depending on the parameters of the model, and so could be the dark matter [271]. The neutralino mass matrix in the $\psi^0 = (\tilde{B}, \tilde{W}^0, \tilde{H}_d^0, \tilde{H}_u^0, \tilde{S})$ gauge-eigenstate basis is:

$$M_{\tilde{N}}^- = \begin{pmatrix} M_1 & 0 & -g'v_d/\sqrt{2} & g'v_u/\sqrt{2} & 0 \\ 0 & M_2 & g'v_d/\sqrt{2} & -g'v_u/\sqrt{2} & 0 \\ -g'v_d/\sqrt{2} & g'v_d/\sqrt{2} & 0 & -\lambda s & -\lambda v_d \\ g'v_u/\sqrt{2} & -g'v_u/\sqrt{2} & -\lambda s & 0 & -\lambda v_u \\ 0 & 0 & -\lambda v_u & -\lambda v_d & 2\kappa s \end{pmatrix}. \quad (10.9)$$

[Compare eq. (7.30).] For small $v/s$ and $\lambda v/\kappa s$, mixing effects of the singlet Higgs and singlino are small, and they nearly decouple. In that case, the phenomenology of the NMSSM is almost indistinguishable from that of the MSSM. For larger $\lambda$, the mixing is important and the experimental signals for sparticles and the Higgs scalars can be altered in important ways [270–273, 192].

### 10.3 Extra $D$-term contributions to scalar masses

Another way to generalize the MSSM is to include additional gauge interactions. The simplest possible gauge extension introduces just one new Abelian gauge symmetry; call it $U(1)_X$. If it is broken at a very high mass scale, then the corresponding vector gauge boson and gaugino fermion will both be heavy and will decouple from physics at the TeV scale and below. However, as long as the MSSM fields carry $U(1)_X$ charges, the breaking of $U(1)_X$ at an arbitrarily high energy scale can still leave a telltale imprint on the soft terms of the MSSM [275].

To see how this works, let us consider the scalar potential for a model in which $U(1)_X$ is broken. Suppose that the MSSM scalar fields, denoted generically by $\phi_i$, carry $U(1)_X$ charges $x_i$. We also introduce a pair of chiral supermultiplets $S_+$ and $S_-$ with $U(1)_X$ charges normalized to $+1$ and $-1$ respectively. These fields are singlets under the Standard Model gauge group $SU(3)_C \times SU(2)_L \times U(1)_Y$, so that when they get VEVs, they will just accomplish the breaking of $U(1)_X$. An obvious guess for the superpotential containing $S_+$ and $S_-$ is $W = MS_+S_-$, where $M$ is a supersymmetric mass. However, unless $M$ vanishes or is very small, it will yield positive-semidefinite quadratic terms in the scalar potential of the form $V = |M|^2(|S_+|^2 + |S_-|^2)$, which will force the minimum to be at $S_+ = S_- = 0$. Since we want $S_+$ and $S_-$ to obtain VEVs, this is unacceptable. Therefore we assume that $M$ is 0 (or very small) and that the leading contribution to the superpotential comes instead from a non-renormalizable term, say:

$$W = \frac{\lambda}{2M_P} S_+^2 S_-^2. \quad (10.10)$$

(Non-renormalizable terms in the superpotential obey the same rules found in section 10.2 in particular, they must be analytic in the chiral superfields. See the Appendix for more details on non-renormalizable Lagrangians in supersymmetric theories.) The equations of motion for the auxiliary fields are then $F_{S_+}^a = -\partial W/\partial S_+ = -(\lambda/M_P)S_+S_-^2$ and $F_{S_-}^a = -\partial W/\partial S_- = -(\lambda/M_P)S_-S_+^2$, and the corresponding contribution to the scalar potential is

$$V_F = |F_{S_+}|^2 + |F_{S_-}|^2 = \frac{|\lambda|^2}{M_P^2}\left(|S_+|^4|S_-|^2 + |S_-|^4|S_+|^2\right). \quad (10.11)$$

In addition, there are supersymmetry-breaking terms that must be taken into account:

$$V_{\text{soft}} = m_+^2|S_+|^2 + m_-^2|S_-|^2 - \left(\frac{a}{2M_P} S_+^2 S_-^2 + \text{c.c.}\right). \quad (10.12)$$
The terms with \( m_U^2 \) and \( m_D^2 \) are soft squared masses for \( S_+ \) and \( S_- \). They could come from a minimal supergravity framework at the Planck scale, but in general they will be renormalized differently, due to different interactions for \( S_+ \) and \( S_- \), which we have not bothered to write down in eq. (10.10) because they involve fields that will not get VEVs. The last term is a “soft” term analogous to the \( a \) terms in the second line of eq. (4.1), with \( a \) of order \( m_{soft}^2 \). The coupling \( a/2M_P \) is actually dimensionless, but should be treated as soft because of its origin and its tiny magnitude. Such terms arise from the supergravity Lagrangian in an exactly analogous way to the usual soft terms. Usually one can just ignore them, but this one plays a crucial role in the gauge symmetry breaking mechanism. The scalar potential for terms containing \( S_+ \) and \( S_- \) is:

\[
V = \frac{1}{2}g_X^2 \left( |S_+|^2 - |S_-|^2 + \sum_i x_i |\phi_i|^2 \right)^2 + V_F + V_{soft}. \tag{10.13}
\]

The first term involves the square of the \( U(1)_X \) D-term [see eqs. (3.74) and (3.75)], and \( g_X \) is the \( U(1)_X \) gauge coupling. The scalar potential eq. (10.13) has a nearly \( D \)-flat direction, because the \( D \)-term part vanishes for \( \phi_i = 0 \) and any \( |S_+| = |S_-| \). Without loss of generality, we can take \( a \) and \( \lambda \) to both be real and positive for purposes of minimizing the scalar potential. As long as \( a^2 - 6\lambda^2(m_U^2 + m_D^2) > 0 \), there is a minimum of the potential very near the flat direction:

\[
\langle S_+ \rangle^2 \approx \langle S_- \rangle^2 \approx \left[ a + \sqrt{a^2 - 6\lambda^2(m_U^2 + m_D^2)} \right] M_P / 6\lambda^2 \tag{10.14}
\]

(with \( \langle \phi_i \rangle = 0 \), so \( \langle S_+ \rangle \approx \langle S_- \rangle \approx O(\sqrt{m_{soft}^2 M_P}) \). This is also a global minimum of the potential if \( a^2 - 8\lambda^2(m_U^2 + m_D^2) > 0 \). Note that \( m_U^2 + m_D^2 < 0 \) is a sufficient, but not necessary, condition. The \( V_F \) contribution is what stabilizes the scalar potential at very large field strengths. The VEVs of \( S_+ \) and \( S_- \) will typically be of order \( 10^{10} \) GeV or so. Therefore the \( U(1)_X \) gauge boson and gaugino, with masses of order \( g_X \langle S_+ \rangle \), will play no role in collider physics.

However, there is also necessarily a small deviation from \( \langle S_+ \rangle = \langle S_- \rangle \), as long as \( m_U^2 \neq m_D^2 \). At the minimum of the potential with \( \partial V / \partial S_+ = \partial V / \partial S_- = 0 \), the leading order difference in the VEVs is given by

\[
\langle S_+ \rangle^2 - \langle S_- \rangle^2 = -\langle D_X \rangle / g_X \approx (m^2 - m_U^2) / 2g_X^2, \tag{10.15}
\]

assuming that \( \langle S_+ \rangle \) and \( \langle S_- \rangle \) are much larger than their difference. After integrating out \( S_+ \) and \( S_- \) by replacing them using their equations of motion expanded around the minimum of the potential, one finds that the MSSM scalars \( \phi_i \) each receive a squared-mass correction

\[
\Delta m_i^2 = -x_i g_X \langle D_X \rangle, \tag{10.16}
\]

in addition to the usual soft terms from other sources. The \( D \)-term corrections eq. (10.16) can be roughly of the order of \( m_{soft}^2 \) at most, since they are all proportional to \( m^2 - m_U^2 \). The result eq. (10.16) does not actually depend on the choice of the non-renormalizable superpotential, as long as it produces the required symmetry breaking with large VEVs; this is a general feature. The most important feature of eq. (10.16) is that each MSSM scalar squared mass obtains a correction just proportional to its charge \( x_i \) under the spontaneously broken gauge group, with a universal factor \( g_X \langle D_X \rangle \). In a sense, the soft supersymmetry-breaking terms \( m_U^2 \) and \( m_D^2 \) have been recycled into a non-zero \( D \)-term for \( U(1)_X \), which then leaves its “fingerprint” on the spectrum of MSSM scalar masses. From the point of view of TeV scale physics, the quantity \( g_X \langle D_X \rangle \) can simply be taken to parameterize our ignorance of how \( U(1)_X \) got broken. Typically, the charges \( x_i \) are rational numbers and do not all have the same sign, so that a particular candidate \( U(1)_X \) can leave a quite distinctive pattern of mass splittings on the squark and slepton spectrum. As long as the charges are family-independent, the squarks and sleptons
with the same electroweak quantum numbers remain degenerate, maintaining the natural suppression of flavor-mixing effects.

The additional gauge symmetry $U(1)_X$ in the above discussion can stand alone, or may perhaps be embedded in a larger non-Abelian gauge group. If the gauge group for the underlying theory at the Planck scale contains more than one new $U(1)$ factor, then each can make a contribution like eq. (10.16). Additional $U(1)$ gauge groups are quite common in superstring models, suggesting optimism about the existence of corresponding $D$-term corrections. Once one merely assumes the existence of additional $U(1)$ gauge groups at very high energies, it is unnatural to assume that such $D$-term contributions to the MSSM scalar masses should vanish, unless there is an exact symmetry that enforces $m_+^2 = m_-^2$. The only question is whether or not the magnitude of the $D$-term contributions is significant compared to the usual minimal supergravity and RG contributions. So efforts to understand the sparticle spectrum of the MSSM may need to take into account the possibility of $D$-terms from additional gauge groups.

11 Concluding remarks

In this primer, I have attempted to convey some of the more essential features of supersymmetry as it is understood so far. One of the most amazing qualities of supersymmetry is that so much is known about it already, despite the present lack of direct experimental data. Even the terms and stakes of many of the important outstanding questions, especially the paramount issue “How is supersymmetry broken?”, are already rather clear. That this can be so is a testament to the unreasonably predictive quality of the symmetry itself.

We have seen that sensible and economical models for supersymmetry at the TeV scale can be used as convenient templates for experimental searches. Two of the simplest and most popular possibilities are the “minimal supergravity” scenario with new parameters $m_0^2$, $m_{1/2}$, $A_0$, $\tan \beta$ and $\text{Arg}(\mu)$, and the “gauge-mediated” scenario with new parameters $\Lambda$, $M_{\text{mess}}$, $N_5$, $\langle F \rangle$, $\tan \beta$, and $\text{Arg}(\mu)$. However, one should not lose sight of the fact that the only indispensable idea of supersymmetry is simply that of a symmetry between fermions and bosons. Nature may or may not be kind enough to realize this beautiful idea within one of the specific frameworks that have already been explored well by theorists.

The experimental verification of supersymmetry will not be an end, but rather a revolution in high energy physics. It seems likely to present us with questions and challenges that we can only guess at presently. The measurement of sparticle masses, production cross-sections, and decay modes will rule out some models for supersymmetry breaking and lend credence to others. We will be able to test the principle of $R$-parity conservation, the idea that supersymmetry has something to do with the dark matter, and possibly make connections to other aspects of cosmology including baryogenesis and inflation. Other fundamental questions, like the origin of the $\mu$ parameter and the rather peculiar hierarchical structure of the Yukawa couplings may be brought into sharper focus with the discovery of the MSSM spectrum. Understanding the precise connection of supersymmetry to the electroweak scale will surely open the window to even deeper levels of fundamental physics.

Appendix: Non-renormalizable supersymmetric Lagrangians

In section 3 we discussed only renormalizable supersymmetric Lagrangians. However, like all known theories that include general relativity, supergravity is non-renormalizable as a quantum field theory. It is therefore clear that non-renormalizable interactions must be present in any low-energy effective description of the MSSM. Fortunately, these can be neglected for most phenomenological purposes, because non-renormalizable interactions have couplings of negative mass dimension, proportional to powers of $1/M_P$ (or perhaps $1/\Lambda_{\text{UV}}$, where $\Lambda_{\text{UV}}$ is some other cutoff scale associated with new physics). This means that their effects at energy scales $E$ ordinarily accessible to experiment are typically
suppressed by powers of $E/M_P$ (or by powers of $E/\Lambda_{\text{UV}}$). For energies $E \lesssim 1 \text{ TeV}$, the consequences of non-renormalizable interactions are therefore usually far too small to be interesting.

Still, there are several reasons why one might be interested in non-renormalizable contributions to supersymmetric Lagrangians. First, some very rare processes (like proton decay) can only be described using an effective MSSM Lagrangian that includes non-renormalizable terms. Second, one may be interested in understanding physics at very high energy scales where the suppression associated with non-renormalizable terms is not enough to stop them from being important. For example, this could be the case in the study of the very early universe, or in understanding how additional gauge symmetries get broken. Third, the non-renormalizable interactions may play a crucial role in understanding how supersymmetry breaking is transmitted to the MSSM. Finally, it is sometimes useful to treat strongly coupled supersymmetric gauge theories using non-renormalizable effective Lagrangians, in the same way that chiral effective Lagrangians are used to study hadron physics in QCD. Unfortunately, we will not be able to treat these subjects in any sort of systematic way. Instead, we will merely sketch a few of the key elements that go into defining a non-renormalizable supersymmetric Lagrangian. More detailed treatments may be found for example in refs. [12, 16, 18, 20, 26, 28, 29].

Let us consider a supersymmetric theory containing gauge and chiral supermultiplets whose Lagrangian may contain terms that are non-renormalizable. This includes supergravity as a special case, but applies more generally. It turns out that the part of the Lagrangian containing terms with up to two spacetime derivatives is completely determined by specifying three functions of the complex scalar fields (or more formally, of the chiral superfields). They are:

- The superpotential $W(\phi_i)$, which we have already encountered in the case of renormalizable supersymmetric Lagrangians. It must be an analytic function of the superfields treated as complex variables; in other words it depends only on the $\phi_i$ and not on the $\phi^*i$. It must be invariant under the gauge symmetries of the theory, and has dimensions of $[\text{mass}]^3$.

- The Kähler potential $K(\phi_i, \phi^*i)$. Unlike the superpotential, the Kähler potential is a function of both $\phi_i$ and $\phi^*i$. It is gauge-invariant, real, and has dimensions of $[\text{mass}]^2$. In the special case of renormalizable theories, we did not have to discuss the Kähler potential explicitly, because at tree-level it is always $K = \phi^*i \phi_i$ (with $i$ summed over as usual).

- The gauge kinetic function $f_{ab}(\phi_i)$. Like the superpotential, it is an analytic function of the $\phi_i$ treated as complex variables. It is dimensionless and symmetric under interchange of its two indices $a,b$, which run over the adjoint representations of the gauge groups of the model. In the special case of renormalizable supersymmetric Lagrangians, it is just a constant (independent of the $\phi_i$), and is equal to the identity matrix divided by the gauge coupling squared: $f_{ab} = \delta_{ab}/g_a^2$. More generally, it also determines the non-renormalizable couplings of the gauge supermultiplets.

The whole Lagrangian with up to two derivatives can now be written down in terms of these. This is a non-trivial consequence of supersymmetry, because many different individual couplings in the Lagrangian are determined by the same three functions.

For example, in supergravity models, the part of the scalar potential that does not depend on the gauge kinetic function can be found as follows. First, one may define the real, dimensionless Kähler function:

$$G = K/M_P^2 + \ln(W/M_P^2) + \ln(W^*/M_P^2).$$  \hfill (A.1)

(Just to maximize the confusion, $G$ is also sometimes referred to as the Kähler potential. Also, many references use units with $M_P = 1$, which simplifies the expressions but can slightly obscure the correspondence with the global supersymmetry limit of large $M_P$.) From $G$, one can construct its derivatives with respect to the scalar fields and their complex conjugates: $G_i = \delta G/\delta \phi_i^*$; $G^i = \delta G/\delta \phi^i$; and
$G^i_j = \delta^2 G / \delta \phi^i \delta \phi_j$. As in section 3.2 raised (lowered) indices $i$ correspond to derivatives with respect to $\phi_i$ ($\phi^i$). Note that $G^i_j = K^i_j / M_P^2$, which is sometimes called the Kähler metric, does not depend on the superpotential. The inverse of this matrix is denoted $(G^{-1})^i_j$, or equivalently $M_P^2 (K^{-1})^i_j$, so that $(G^{-1})^i_j G^k_i = (G^{-1})^i_j G^i_k = \delta^j_k$. In terms of these objects, the generalization of the $F$-term contribution to the scalar potential in ordinary renormalizable global supersymmetry turns out to be, after a complicated derivation [129, 130]:

$$V_F = M_P^4 e^G \left[ G^i (G^{-1})^i_j G_j - 3 \right]$$

(A.2)

in supergravity. It can be rewritten as

$$V_F = K^i_j F_j F^{*i} - 3 e^{K/M_P^2} WW^*/M_P^2,$$

(A.3)

where

$$F_i = -M_P^2 e^{G/2} (G^{-1})^i_j G_j = -e^{K/2M_P^2} (K^{-1})^i_j \left[ W^* + W^* K_j / M_P^2 \right],$$

(A.4)

with $K^i = \delta K / \delta \phi_i$ and $K_j = \delta K / \delta \phi^j$. The $F_i$ are order parameters for supersymmetry breaking in supergravity (generalizing the auxiliary fields in the renormalizable global supersymmetry case). In other words, local supersymmetry will be broken if one or more of the $F_i$ obtain a VEV. The gravitino then absorbs the would-be goldstino and obtains a squared mass

$$m_R^2 = (K^i_j F_i F^{*j}) / 3M_P^2.$$  

(A.5)

Now, assuming a minimal Kähler potential $K = \phi^{*i} \phi_i$, then $K^i_j = (K^{-1})^i_j = \delta^i_j$, so that expanding eqs. (A.3) and (A.4) to lowest order in $1/M_P$ just reproduces the results $F_i = -W^*_i$ and $V = F_i F^{*i} = W^* W^*_i$, which were found in section 3.2 for renormalizable global supersymmetric theories [see eqs. (3.48), (3.50)]. Equation (A.5) also reproduces the expression for the gravitino mass that was quoted in eq. (6.31).

The scalar potential eq. (A.2) does not include the $D$-term contributions from gauge interactions, which are given by

$$V_D = \frac{1}{2} \text{Re} [f_{ab}^{-1} \hat{D}_a \hat{D}_b],$$

(A.6)

where

$$\hat{D}^a \equiv -G^i (T^a)_i \phi_j = -\phi^{*j} (T^a)_j \phi_j = -K^i (T^a)_i \phi_j = -\phi^{*j} (T^a)_j K^i,$$

(A.7)

are real order parameters of supersymmetry breaking, with the last three equalities following from the gauge invariance of $W$ and $K$. The full scalar potential is

$$V = V_F + V_D,$$

(A.8)

and it depends on $W$ and $K$ only through the combination $G$ in eq. (A.1). There are many other contributions to the supergravity Lagrangian, which also turn out to depend only on $G$ and $f_{ab}$, and can be found in ref. [129, 130]. This allows one to consistently redefine $W$ and $K$ so that there are no purely holomorphic or purely anti-holomorphic terms appearing in the latter.

Note that in the tree-level global supersymmetry case $f_{ab} = \delta_{ab} / g_a^2$ and $K^i = \phi^{*i}$, eq. (A.6) reproduces the result of section 3.4 for the renormalizable global supersymmetry $D$-term scalar potential, with $\hat{D}^a = D^a / g^a$ being the $D$-term order parameter for supersymmetry breaking.

Unlike in the case of global supersymmetry, the scalar potential in supergravity is not necessarily non-negative, because of the $-3$ term in eq. (A.2). Therefore, in principle, one can have supersymmetry
breaking with a positive, negative, or zero vacuum energy. Recent developments in experimental cosmology imply a positive vacuum energy associated with the acceleration of the scale factor of the observable universe,

$$\rho_{\text{observed}} = \frac{\Lambda}{8\pi G_{\text{Newton}}} \approx (2.3 \times 10^{-12} \text{ GeV})^4,$$  \hspace{1cm} (A.9)

but this is also certainly tiny compared to the scales associated with supersymmetry breaking. Therefore, it is tempting to simply assume that the vacuum energy is 0 within the approximations pertinent for working out the supergravity effects on particle physics at high energies. However, it is notoriously unclear why the terms in the scalar potential in a supersymmetry-breaking vacuum should conspire to give \( \langle V \rangle \approx 0 \) at the minimum. A naive estimate, without miraculous cancellations, would give instead \( \langle V \rangle \) of order \( \langle |F|^2 \rangle \), so at least roughly \( (10^{10} \text{ GeV})^4 \) for Planck-scale mediated supersymmetry breaking, or \( (10^4 \text{ GeV})^4 \) for Gauge-mediated supersymmetry breaking. Furthermore, while \( \rho_{\text{vac}} = \langle V \rangle \) classically, the former is a very large-distance scale measured quantity, while the latter is associated with effective field theories at length scales comparable to and shorter than those familiar to high energy physics. So, in the absence of a compelling explanation for the tiny value of \( \rho_{\text{vac}} \), it is not at all clear that \( \langle V \rangle \approx 0 \) is really the right condition to impose \[\text{[276]}. \] Nevertheless, with \( \langle V \rangle = 0 \) imposed as a constraint, \[\text{\dag} \]
eqs \[\text{[A.3] - A.5] \] tell us that \( \langle K_j^i F_i^* X \rangle = 3M_P^2 e^{(G)} = 3e^{(K)/M_P^2} \langle \langle W \rangle \rangle^2/M_P^2 \), and an equivalent formula for the gravitino mass is therefore \( m_{3/2} = e^{(G)/2} M_P \).

An instructive special case arises if we assume a minimal Kähler potential and divide the fields \( \phi_i \) into a visible sector including the MSSM fields \( \phi_i \), and a hidden sector containing a field \( X \) that breaks supersymmetry for us (and other fields that we need not treat explicitly). In other words, suppose that the superpotential and the Kähler potential have the form

\[ W = W_{\text{vis}}(\phi_i) + W_{\text{hid}}(X), \]  \hspace{1cm} (A.10)

\[ K = \varphi^i \phi_i + X^* X. \]  \hspace{1cm} (A.11)

Now let us further assume that the dynamics of the hidden sector fields provides non-zero VEVs

\[ \langle X \rangle = x M_P, \] \hspace{1cm} \[ \langle W_{\text{hid}} \rangle = w M_P^2, \] \hspace{1cm} \[ \langle \delta W_{\text{hid}}/\delta X \rangle = w'M_P, \]  \hspace{1cm} (A.12)

which define a dimensionless quantity \( x \), and \( w, w' \) with dimensions of [mass]. Requiring \( \langle V \rangle = 0 \) yields \( |w' + x^* w|^2 = 3|w|^2 \), and

\[ m_{3/2} = |\langle F_X \rangle|/\sqrt{3} M_P = e^{|x|^2/2}|w|. \]  \hspace{1cm} (A.13)

Now we suppose that it is valid to expand the scalar potential in powers of the dimensionless quantities \( w/M_P, w'/M_P, \phi_i/M_P \), etc., keeping only terms that depend on the visible sector fields \( \phi_i \). It is not a difficult exercise to show that in leading order the result is:

\[ V = (W_{\text{vis}}^*)^i (W_{\text{vis}})^i + m_{3/2}^2 \varphi^i \phi_i \]  
\[ + e^{ix^2/2} \left[ w^* \phi_i (W_{\text{vis}})^i + (x^* w + |x|^2 w^* - 3w^*) W_{\text{vis}} + \text{c.c.} \right]. \]  \hspace{1cm} (A.14)

A tricky point here is that we have rescaled the visible sector superpotential \( W_{\text{vis}} \rightarrow e^{-|x|^2/2} W_{\text{vis}} \) everywhere, in order that the first term in eq. \[\text{[A.14]} \] is the usual, properly normalized, \( F \)-term contribution in global supersymmetry. The next term is a universal soft scalar squared mass of the form eq. \[\text{[6.39]} \] with

\[ m_0^2 = |\langle F_X \rangle|^2/3M_P^2 = m_{3/2}^2. \]  \hspace{1cm} (A.15)

\[\text{\dag} \] We do this only to follow popular example; as just noted we cannot endorse this imposition.
The second line of eq. (A.14) just gives soft (scalar)\(^3\) and (scalar)\(^2\) analytic couplings of the form eqs. (6.40) and (6.41), with

\[ A_0 = -x^s \langle F_X \rangle / M_P, \quad B_0 = \left( \frac{1}{x + w^s / w^s} - x^s \right) \langle F_X \rangle / M_P \] (A.16)

since \( \varphi_i (W_{\text{vis}})^i \) is equal to \( 3W_{\text{vis}} \) for the cubic part of \( W_{\text{vis}} \), and to \( 2W_{\text{vis}} \) for the quadratic part. [If the complex phases of \( x, w, w' \) can be rotated away, then eq. (A.16) implies \( B_0 = A_0 - m_{3/2}^3 \), but there are many effects that can ruin this prediction.] The Polonyi model mentioned in section 6.6 is just the special case of this exercise in which \( W_{\text{hid}} \) is assumed to be linear in \( X \).

However, there is no particular reason why \( W \) and \( K \) must have the simple form eq. (A.10) and eq. (A.11). In general, the superpotential can be expanded like

\[ W = W_{\text{ren}} + \frac{1}{M_P} w^{i j k n} \phi_i \phi_j \phi_k \phi_n + \frac{1}{M_P^2} w^{i j k m n} \phi_i \phi_j \phi_k \phi_n \phi_m + \ldots \] (A.17)

where \( W_{\text{ren}} \) is the renormalizable superpotential with terms up to \( \phi^3 \). Similarly, the Kähler potential can be expanded like

\[ K = \phi_i \phi^s i + \frac{1}{M_P} (k_{ij}^{ij} \phi_i \phi_j \phi^s k + \text{c.c.}) + \frac{1}{M_P^2} (k_{ij}^{ij} \phi_i \phi_j \phi^s k \phi^s n + k_{ij}^{ij} \phi_i \phi_j \phi^s k \phi^s n + \text{c.c.}) + \ldots, \] (A.18)

where terms in \( K \) that are analytic in \( \phi \) (and \( \phi^* \)) are assumed to have been absorbed into \( W \) (and \( W^* \)), as explained above. The form of the first term is dictated by the requirement of canonical kinetic terms for the chiral supermultiplet fields. If one now plugs eqs. (A.17) and (A.18) with arbitrary hidden sector fields and VEVs into eq. (A.2), one obtains a general form like eq. (6.35) for the soft terms. It is only when special assumptions are made [like eqs. (A.10), (A.11)] that one gets the phenomenologically desirable results in eqs. (6.37)-(6.41). Thus supergravity by itself does not guarantee universality of the soft terms. Furthermore, there is no guarantee that expansions in \( 1/M_P \) of the form given above are valid or appropriate. In superstring models, the dilaton and moduli fields have Kähler potential terms proportional to \( M_P^2 \ln[(\phi + \phi^*)/M_P] \). (The moduli are massless fields that do not appear in the tree-level perturbative superpotential. The dilaton is a special modulus field whose VEV determines the gauge couplings in the theory.)

Gaugino masses arise from non-renormalizable terms through a non-minimal gauge kinetic function \( f_{ab} \). Expanding it in powers of \( 1/M_P \) as

\[ f_{ab} = \delta_{ab} \left[ 1/g_a^2 + f_{ab}^i \phi_i / M_P + \ldots \right], \] (A.19)

it is possible to show that the gaugino mass induced by supersymmetry breaking is

\[ m_{\lambda^a} = \text{Re}\{f_{ab}^i \langle F_i \rangle / 2M_P \}. \] (A.20)

The assumption of universal gaugino masses therefore follows if the dimensionless quantities \( f_{ab}^i \) are the same for each of the three MSSM gaugino groups; this is automatic in certain GUT and superstring-inspired models, but not in general.

Finally, let us mention how gaugino condensates can provide supersymmetry breaking in supergravity models. This again requires that the gauge kinetic function has a non-trivial dependence on the scalar fields, as in eq. (A.19). Then eq. (A.4) is modified to

\[ F_i = -M_P^2 e^{G^2 / 2} (G^{-1})_i^j G_j - \frac{1}{4} (K^{-1})_i^j \frac{\partial f_{ab}}{\partial \phi^a} \lambda^a \lambda^b + \ldots \] (A.21)

Now if there is a gaugino condensate \( \langle \lambda^a \lambda^b \rangle = \delta^{ab} \Lambda^3 \) and \( \langle (K^{-1})_i^j \partial f_{ab} / \partial \phi_j \rangle \sim 1/M_P \), then \( \langle F_i \rangle \sim \Lambda^3 / M_P \). Then as above, the non-vanishing \( F \)-term gives rise to soft parameters of order \( m_{\text{soft}} \sim \langle F_i \rangle / M_P \sim \Lambda^3 / M_P^2 \), as in eq. (6.26).
Acknowledgments

This is an extended and revised version of a chapter appearing in the volume *Perspectives on Supersymmetry* (World Scientific, 1998) at the kind invitation of Gordy Kane. I am thankful to him and to James Wells for many helpful comments and suggestions on this primer. I am also indebted to my other collaborators on supersymmetry and related matters, Sandro Ambrosanio, Nima Arkani-Hamed, Diego Castaño, Ray Culbertson, Michael Dine, Manuel Drees, Herbi Dreiner, Tony Gherghetta, Howie Haber, Ian Jack, Tim Jones, Chris Kolda, Graham Kribs, Stefano Moretti, Steve Mrenna, Jian-ming Qian, Dave Robertson, Scott Thomas, Kazuhiro Tobe, Mike Vaughn, Graham Wilson, Youichi Yamada, and especially Pierre Ramond, for many illuminating and inspiring conversations. Corrections to previous versions have been provided by Gudrun Hiller, Graham Kribs, Bob McElrath, Verónica Sanz, Shufang Su, John Terning, Keith Thomas, Scott Thomas, and Sean Tulin. I will be grateful to receive further corrections at spmartin@niu.edu, and a list of them will be maintained at http://zippy.physics.niu.edu/primer.html. I thank the Aspen Center for Physics and the Stanford Linear Accelerator Center for their hospitality, and the students of PHYS 686 at NIU in Spring 2004 and the 2005 ICTP Summer School on Particle Physics for asking interesting questions. This work was supported in part by the U.S. Department of Energy, and by NSF grants PHY-9970691, PHY-0140129, and PHY-0456635.
